# Resumo

Lógicas modais têm sido estudadas na Ciência da Computação por permitirem a caracterização de sistemas complexos, envolvendo noções tais como conhecimento e crença, por exemplo. Neste trabalho, focamos no provador de teoremas para a lógica multimodal básica  $K_n$ : KSP, que implementa um método de provas baseado em resolução clausal. Cláusulas são rotuladas pelo nível modal em que ocorrem, auxiliando a restringir aplicações desnecessárias das regras de inferência. KSP apresenta uma boa performance se o conjunto de símbolos proposicionais estão bem distribuídos entre os níveis modais. Entretanto, quando há um grande número de variáveis em um nível específico, o tempo de execução aumenta. Uma das razões é que a transformação para a forma normal utilizada sempre gera conjuntos satisfatíveis de cláusulas proposicionais. Isto pode acarretar em uma significativa perda de performance, uma vez que resolução é baseada em saturação. Atualmente, estamos investigando o uso de provadores para o problema de Satisfatibilidade Booleana, ou SAT *solvers*, uma vez que já se mostraram capazes de resolver eficientemente problemas difíceis. Acreditamos poder utilizar as técnicas desenvolvidas depois de décadas de esforços práticos e teóricos direcionados a estes provadores. Nossa implementação, que é um trabalho em andamento, utiliza um SAT *solver* baseado em aprendizado de cláusulas através de análise de conflito. Damos como entrada a este *solver*, o conjunto satisfatível de cláusulas gerado pela transformação e, toda vez que um conflito é identificado, uma ou mais cláusulas são aprendidas pelo procedimento de análise de conflito. Acreditamos que, cuidadosamente escolhendo o conjunto de cláusulas e usando as cláusulas aprendidas geradas pelo *solver*, podemos reduzir o tempo que KSP gasta durante a saturação.

**Palavras-chave:** lógica modal, resolução, saturação, sat-solvers

# Abstract

Modal logics have been widely studied in Computer Science for allowing the characterization of complex systems that express notions in terms of knowledge, belief etc. In this work, we focus on the theorem prover for the basic multimodal language  $K_n$ : KSP, which implements a clausal resolution method. Clauses are labelled by the modal level at which they occur, helping to restrict unnecessary applications of the resolution inference rules. KSP performs well if the set of propositional symbols are uniformly distributed over the modal levels. However, when there is a high number of variables in just one particular level, the performance deteriorates. One reason is that the specific normal form we use always generates satisfiable sets of propositional clauses. As resolution relies on saturation, this can be very time consuming. We are currently investigating the use of Boolean Satisfiability Solvers (SAT solvers), since they are able to solve hard structured problems with several variables and constraints. We believe that we can take advantage of the efforts that have been directed in improving the efficiency of such solvers. Our implementation, which is work in progress, uses a SAT solver based on clause learning by conflict analysis. We feed this solver with the satisfiable sets of clauses generated by translation and, each time it identifies a conflict, one or more new clauses are learnt from the conflict analysis procedure. We believe that by carefully choosing the set of clauses and making use of the learnt clauses generated by the solver, we may be able to reduce the time KSP spends during saturation.

## Introduction

Several aspects of complex computational systems can be modelled by means of logic languages, allowing for the characterization of notions such as probabilities, possibilities, time, knowledge and beliefs [24, 33, 34, 48]. Modal logics, more specifically, have been widely studied in Computer Science as they can naturally model, for instance, notions of knowledge and belief in multiagent systems [13, 24, 48], and temporal aspects in the formal verification of problems related to concurrent and distributed systems [33, 34]. Modal languages are simple yet expressive languages for reasoning over relations between different contexts or interpretations [12].

Once a system has been specified in a logic language, it is possible to use proof methods to verify properties of such system. In general, if  $\mathcal{I}$  is the formulae set representing the implementation, and  $\mathcal{F}$  is the set that characterizes the specification, the verification process consists in showing that it is possible to *derive* the specified aspects in  $\mathcal{F}$  from  $\mathcal{I}$ . Each proof system defines a particular approach to deal with formulae. Furthermore, it is possible to combine proof methods with the ultimate goal to benefit from each method's advantages.

In the literature, we find several successful combinations of logical systems (e.g. [3, 27, 31, 32]). Combination of logic languages may increase the computational complexity of the problem, or even lead to the undecidability of the resultant logic satisfiability [26]. Therefore, it is essential to develop reliable techniques that allow the uniform implementation of combined proof systems for such combination of logic languages.

The satisfiability problem for the basic multimodal logic  $K_n$  is proven to be PSPACE-complete [56], for local satisfiability, and EXPTIME, for global satisfiability [56]. In [45], a complete calculus based on modal levels, for both local and global reasoning for the multimodal basic propositional modal logic, is presented. The strategies introduced in [45] helps to reduce the search space for a proof and also reduces the number of inference rules needed in the calculus. The implementation of theses strategies showed that the

partitioning in modal levels may decrease the time spent during proofs [46].

In the literature, there are several other theorem provers for modal logics [3, 50, 57, 58]. In this work, we focus on KSP [46], a theorem prover for the modal language  $K_n$ , which implements the clausal resolution method proposed in [45]. Clauses are labelled by the modal level at which they occur, helping to restrict unnecessary applications of the resolution inference rules. In order to reduce the search space for a proof, several refinements and simplification techniques are implemented as part of KSP. To get the best performance for a particular formula, or class of formulae, it is important to choose the right strategy and optimizations.

According to [46], KSP performs well if the set of propositional symbols are uniformly distributed over the modal levels. However, when there is a high number of propositional symbols in just one particular level, the performance deteriorates. One reason is that the specific normal form used always generates satisfiable sets of propositional clauses (i.e. clauses without modal operators). As resolution relies on saturation, this can be very time consuming. We are currently investigating the use of other tools in order to speed up the saturation process.

Boolean Satisfiability Solvers (SAT solvers), for instance, can often solve hard structured problems with over a million variables and several million constraints [29]. We believe that we can take advantage of the theoretical and practical efforts that have been directed in improving the efficiency of such solvers for helping to speed the saturation process within the procedures already implemented in KSP.

One of the main reasons for the widespread use of SAT in many applications is that solvers based on clause learning are very effective in practice [29]. The main idea behind Conflict-Driven Clause Learning (CDCL) is to cache “causes of conflict” as learned clauses, and to utilize this information to prune the search in a different part of the search space encountered later. Since their inception in the mid-90s, CDCL SAT solvers have been applied, in many cases with remarkable success, to a number of practical applications [11].

Our implementation, which is work in progress, uses a SAT solver based on clause learning by conflict analysis. We intend to feed such a solver with the satisfiable set of clauses generated at each modal level by the translation procedure used by KSP. Each time the SAT solver identifies a conflict in these sets due to unit propagation from some variable assignment, one or more new clauses are learnt from the conflict analysis procedure, which analyses the structure of unit propagation and decides which literals to include in the new clauses [11]. As mentioned before, as we already know that these sets are satisfiable, we are not particularly interested in the model generated by the SAT solver.

We will then feed KSP back the new learnt clauses, hoping it can find more applications of the inference rules which deal with modal reasoning. We believe that by carefully

choosing the set of clauses we feed the SAT solver, and appropriately using the learnt clauses generated, we may be able to reduce the time KSP spends during saturation.

The rest of this work is organized as follows: Chapter 2 introduces the propositional modal language which is the main focus of this work,  $K_n$ , as well as its syntax and semantics; Chapter 3 and Chapter 4, present a brief overview of resolution based systems and modern SAT solvers, respectively. Finally, in Chapter 5 we discuss how we pretend to combine KSP with a SAT solver, and what we expect from this combination.

# Chapter 2

## Modal Logics

This chapter formally introduces  $K_n$ , a *propositional modal logic language*, semantically determined by an account of necessity and possibility [44].

In classical logic, propositions or sentences are evaluated to either *true* or *false*, in any model [37]. However, in natural language, we often distinguish between various modalities of truth, such as *necessarily* true, *known to be* true, *believed to be* true or yet true *in some future*, for example.

Modal logics extend classical logic by adding operators, known as *modal operators*, to express one or more of these different modes of truth. Different modalities define different languages [12]. One can think of modal logics, in opposition to propositional logic, for instance, as, “rather than standing outside a relational structure between given contexts, and scanning the information they contain from some celestial vantage point, formulae may be evaluated *inside* these structures, *at a particular state*” [12]. In this sense, the key concept behind the modal operators is to allow us to reason over relations among different contexts or interpretations, an abstraction that here we think as *possible worlds*.

A propositional modal language is the well known propositional logic language augmented by a collection of modal operators [12]. The purpose of these operators is to allow the information that holds at other worlds to be examined — but, crucially, only at worlds visible or accessible from the current one via an accessibility relation [12]. Then, the evaluation of a modal formula depends on the set of possible worlds and the accessibility relations defined over these worlds. This idea will be made precise in Section 2.2, when we define the *satisfiability* of formulae. It is possible to define several accessibility relations between worlds, and different modal logics are defined by different relations.

The modal language which is the focus of this work is the extension of the classical propositional logic plus the unary operators  $\Box_a$  and  $\Diamond_a$ , whose reading are “is necessary from the point of view of an agent *a*” and “is possible from the point of view of an agent *a*”, respectively. This language is known as  $K_n$ . The satisfiability and validity of a formula

in  $K_n$  depend on a structure known as a *Kripke model*, a structure proposed by Kripke to semantically analyse modal logics [38]. A set of worlds, the accessibility relations over these worlds, and a valuation function define a Kripke model.

$K_n$  is characterized by the schema  $\Box_a(\varphi \Rightarrow \psi) \Rightarrow (\Box_a\varphi \Rightarrow \Box_a\psi)$  (axiom K), where  $a$  is an index from a finite, fixed set of *agents*, and  $\varphi, \psi$  are well-formed formulae. The addition of other axioms defines different systems of modal logics and it imposes restrictions on the class of models where formulae are valid [15]. For instance, if we add the formula  $\Box_a\varphi \Rightarrow \Box_a\Box_a\varphi$  (axiom T) as an axiom, formulae will only hold in models whose accessibility relations are reflexive.

Now consider, for example, a Kripke model, its set of possible worlds, the binary accessibility relations, indexed by an agents, and the valuation function that returns the value of a propositional symbol in a specific world of this model. We say that a formula  $\Box_a p$  is satisfiable at some world  $w$ , if the valuation function establishes that  $p$  is true at all worlds accessible from  $w$  through the accessibility relation indexed by the agent  $a$ .

In the following, we will formally define the modal language. The syntax and semantics of  $K_n$  are given in Sections 2.1 and 2.2, respectively, and the definitions presented in these two sections follow those in [44].

## 2.1 Syntax

The language of  $K_n$  is equivalent to its set of *well-formed formulae*, denoted by  $WFF_{K_n}$ , which is constructed from a denumerable set of *propositional symbols* or *variables*  $\mathcal{P} = \{p, q, r, \dots\}$ , the negation symbol  $\neg$ , the disjunction symbol  $\vee$  and the modal connectives  $\Box_a$ , that express the notion of necessity, for each  $a$  in a finite, non-empty fixed set of indexes  $\mathcal{A} = \{1, \dots, n\}$ , where  $n \in \mathbb{N}$ .

**Definition 1** The set of well-formed formulae,  $WFF_{K_n}$ , is the least set such that:

1.  $p \in WFF_{K_n}$ , for all  $p \in \mathcal{P}$
2. if  $\varphi, \psi \in WFF_{K_n}$ , then so are  $\neg\varphi$ ,  $(\varphi \vee \psi)$  and  $\Box_a\varphi$ , for each  $a \in \mathcal{A}$

The operator  $\Diamond$  is the dual of  $\Box_a$ , for each  $a \in \mathcal{A}$ , that is,  $\Diamond\varphi$  can be defined as  $\neg\Box_a\neg\varphi$ , with  $\varphi \in WFF_{K_n}$ . Other logical operators are also used as abbreviations. In this work, we consider the usual ones:

- $\varphi \wedge \psi \stackrel{\text{def}}{=} \neg(\neg\varphi \vee \neg\psi)$  (conjunction)
- $\varphi \Rightarrow \psi \stackrel{\text{def}}{=} \neg\varphi \vee \psi$  (implication)

- $\varphi \Leftrightarrow \psi \stackrel{\text{def}}{=} (\varphi \Rightarrow \psi) \wedge (\psi \Rightarrow \varphi)$  (equivalence)
- $\text{false} \stackrel{\text{def}}{=} \varphi \wedge \neg\varphi$  (*falsum*)
- $\text{true} \stackrel{\text{def}}{=} \neg\text{false}$  (*verum*)

Parentheses may be omitted if the reading is not ambiguous. When  $n = 1$ , we often omit the index in the modal operators, i.e., we just write  $\Box\varphi$  and  $\Diamond\varphi$ , for a well-formed formula  $\varphi$ .

We define a *literal* as a propositional symbol  $p \in \mathcal{P}$  or its negation  $\neg p$ , and denote by  $\mathcal{L}$  the set of all literals. A *modal literal* is a formula of the form  $\Box l$  or  $\Diamond l$ , with  $l \in \mathcal{L}$  and  $a \in \mathcal{A}$ . If  $l$  is a literal, we call  $\neg l$  its complement and say that  $l$  and  $\neg l$  form, in either order, a complementary pair.

The following definitions are also needed later. The *modal depth* of a formula is recursively defined as follows:

**Definition 2** Let  $\varphi$  and  $\psi$  be well-formed formulae. We define  $mdepth : \text{WFF}_{\mathcal{K}_n} \rightarrow \mathbb{N}$  inductively as:

1.  $mdepth(p) = 0$ , for  $p \in \mathcal{P}$
2.  $mdepth(\neg\varphi) = mdepth(\varphi)$
3.  $mdepth(\varphi \vee \psi) = \max\{mdepth(\varphi), mdepth(\psi)\}$
4.  $mdepth(\Box\varphi) = mdepth(\varphi) + 1$

This function represents the maximal number of nesting operators in a formula. For instance, if  $\varphi = \Box\Diamond p \vee \Diamond q$ ,  $a \in \mathcal{A}$ , then  $mdepth(\varphi) = 2$ .

The *modal level* of a formula (or a subformula) is given relative to its position in an *annotated syntactic tree*.

**Definition 3** Let  $\Sigma$  be the alphabet  $\{1, 2, .\}$  and  $\Sigma^*$  the set of all finite sequences over  $\Sigma$ . We define  $\tau : \text{WFF}_{\mathcal{K}_n} \times \Sigma^* \times \mathbb{N} \rightarrow \mathcal{P}(\text{WFF}_{\mathcal{K}_n} \times \Sigma^* \times \mathbb{N})$  as the partial function inductively defined as follows:

1.  $\tau(p, \lambda, ml) = \{(p, \lambda, ml)\}$
2.  $\tau(\neg\varphi, \lambda, ml) = \{(\neg\varphi, \lambda, ml)\} \cup \tau(\varphi, \lambda.1, ml)$
3.  $\tau(\Box\varphi, \lambda, ml) = \{(\Box\varphi, \lambda, ml)\} \cup \tau(\varphi, \lambda.1, ml + 1)$

$$4. \tau(\varphi \vee \psi, \lambda, ml) = \{(\varphi \vee \psi, \lambda, ml)\} \cup \tau(\varphi, \lambda.1, ml) \cup \tau(\psi, \lambda.2, ml)$$

With  $p \in \mathcal{P}$ ,  $\lambda \in \Sigma^*$ ,  $ml \in \mathbb{N}$  and  $\varphi, \psi \in \text{WFF}_{K_n}$ .

The function  $\tau$  applied to  $(\varphi, 1, 0)$  returns the annotated syntactic tree for  $\varphi$ , where each node is uniquely identified by a subformula, its position in the tree (or path order) and its modal level. For instance,  $p$  occurs twice in the formula  $\boxed{a} \diamond (p \wedge \boxed{a} p)$ , at the position 1.1.1, with modal level 2, and again at position 1.1.2.1, with modal level 3.

**Definition 4** Let  $\varphi$  be a formula and let  $\tau(\varphi, 1, 0)$  be its annotated syntactic tree. We define the modal level of a subformula  $\varphi'$  of  $\varphi$  at the position  $\lambda$  as  $mlevel : \text{WFF}_{K_n} \times \text{WFF}_{K_n} \times \Sigma^* \rightarrow \mathbb{N}$ , as: if  $(\varphi', \lambda, ml) \in \tau(\varphi, 1, 0)$  then  $mlevel(\varphi, \varphi', \lambda) = ml$ . Otherwise, it is undefined.

This function represents the maximal number of operators in which scope a subformula occurs.

## 2.2 Semantics

The semantics of  $K_n$  is presented in terms of Kripke structures.

**Definition 5** A Kripke model for the set of propositional variables  $\mathcal{P}$  and the finite set of agents  $\mathcal{A} = \{1, \dots, n\}$  is given by the tuple

$$\mathfrak{M} = (W, w_0, R_1, \dots, R_n, \pi) \quad (2.1)$$

where  $W$  is a non-empty set of possible worlds with a distinguished world  $w_0$ , the root of  $\mathfrak{M}$ ; each  $R_a$ ,  $a \in \mathcal{A}$ , is a binary relation on  $W$ , that is,  $R_a \subseteq W \times W$ , and  $\pi : W \times \mathcal{P} \rightarrow \{\text{false}, \text{true}\}$  is the valuation function that associates to each world  $w \in W$  a truth-assignment to propositional symbols.

We write  $R_a w v$  to denote that  $v$  is accessible from  $w$  through the accessibility relation  $R_a$ , that is  $(w, v) \in R_a$ , and  $R_a^+ w v$ , to mean that  $v$  is reachable from  $w$  through a finite number of steps, that is, there exists a sequence  $(w_1, \dots, w_k)$  of worlds such that  $R_a w_i w_{i+1}$ , for all  $i$ ,  $1 \leq i < k$ , where  $w_1 = w$  and  $w_k = v$ , with  $a \in \mathcal{A}$ ,  $w, v, w_i \in W$  and  $i, k \in \mathbb{N}$ . Note that  $R_a^+$  is the *transitive closure* of  $R_a$ , the least transitive relation that contains all elements of  $R_a$ . In this work, we will also use the *transitive and reflexive closure*, denoted by  $R_a^*$ , the least transitive and reflexive relation that contains all elements of  $R_a$ .

*Satisfiability* and *validity* of a formula are defined in terms of the *satisfiability relation*.

**Definition 6** Let  $\mathfrak{M} = (W, w_0, R_1, \dots, R_n, \pi)$  be a Kripke model,  $w \in W$  and  $\varphi, \psi \in \text{WFF}_{K_n}$ . The *satisfiability relation*, denoted by  $\langle \mathfrak{M}, w \rangle \models \varphi$ , between a world  $w$  and a formula  $\varphi$ , is inductively defined by:

1.  $\langle \mathfrak{M}, w \rangle \models p$  if, and only if,  $\pi(w, p) = \text{true}$ , for all  $p \in \mathcal{P}$ ;
2.  $\langle \mathfrak{M}, w \rangle \models \neg\varphi$  if, and only if,  $\langle \mathfrak{M}, w \rangle \not\models \varphi$ ;
3.  $\langle \mathfrak{M}, w \rangle \models \varphi \vee \psi$  if, and only if,  $\langle \mathfrak{M}, w \rangle \models \varphi$  or  $\langle \mathfrak{M}, w \rangle \models \psi$ ;
4.  $\langle \mathfrak{M}, w \rangle \models \Box\varphi$  if, and only if, for all  $t \in W$ ,  $(w, t) \in R_a$  implies  $\langle \mathfrak{M}, t \rangle \models \varphi$ .

A formula  $\varphi \in \text{WFF}_{K_n}$  is said to be *locally satisfiable* if there exists a Kripke model  $\mathfrak{M} = (W, w_0, R_1, \dots, R_n, \pi)$  such that  $\langle \mathfrak{M}, w_0 \rangle \models \varphi$ . In this case we simply write  $\mathfrak{M} \models_L \varphi$  to mean that  $\mathfrak{M}$  locally satisfies  $\varphi$ . A model  $\mathfrak{M} = (W, w_0, R_1, \dots, R_n, \pi)$  is said to *globally satisfy* a formula  $\varphi$ , denoted  $\mathfrak{M} \models_G \varphi$ , if for all  $w \in W$ , we have  $\langle \mathfrak{M}, w \rangle \models \varphi$ . A formula  $\varphi$  is said to be *globally satisfiable* if there is a model  $\mathfrak{M}$  such that  $\mathfrak{M}$  globally satisfies  $\varphi$ . We say that a set  $\mathcal{F}$  of formulae is locally satisfiable if the conjunction of every  $\varphi \in \mathcal{F}$  is locally satisfiable. Global satisfiability of sets is defined analogously. A formula is said to be *valid* if it is locally satisfiable in all models.

**Example 1.** Let  $\mathfrak{M}$  be the model illustrated in Figure 2.1. Take  $\mathfrak{M} = (W, w_0, R, \pi)$ , for  $p \in \mathcal{P}$  and  $\mathcal{A} = \{1\}$ , where

- (i)  $W = \{w_0, w_1, w_2\}$
- (ii)  $R = \{(w_1, w_1), (w_2, w_2), (w_0, w_1), (w_0, w_2)\}$
- (iii)  $\pi(w, p) = \begin{cases} \text{true} & \text{if } w = w_0 \\ \text{false} & \text{otherwise} \end{cases}$

Note that both  $p$  and  $\Box\neg p$  are satisfied in  $\mathfrak{M}$ . This is a rather simple example to illustrate that, even though some sentence evaluates to true at some world, one can see the same sentence occurring with the opposite valuation through an accessibility relation. This kind of reasoning is not possible in classical propositional logic. Other examples of formulae satisfied by this model are:  $p \wedge \Diamond\neg p$ ,  $\Box\Box\neg p$  and  $\Box\Box\Box\neg p$ .

**Example 2.** (*Tree-like model*) Consider the formula  $\varphi = \Box(p \Rightarrow \Diamond p)$ . The Figure 2.2 contains examples of models that satisfy  $\varphi$ , hence,  $\varphi$  is satisfiable. Note that the model from the Figure 2.2b has a graphical representation equivalent to a tree.

Figure 2.1: Example of a Kripke model for  $K_n$

Figure 2.2: Models that satisfy  $\varphi$  of Example 2

As trees play an important role in Computer Science, we will take this opportunity to define them formally. By a tree  $\mathfrak{T}$  we mean a relational structure  $(T, S)$  where  $T$  is a set of nodes and  $S$  is a binary relation over these nodes.  $T$  contains a unique node  $r_0 \in T$  (called the *root*) such that all other nodes in  $T$  are reachable from  $r_0$ , that is, for all  $t \in T$ , with  $t \neq r_0$ , we have  $S^+ r_0 t$ . Also, every element of  $T$ , distinct from  $r_0$ , has a unique  $S$ -predecessor, and  $S$  is acyclic, that is, for all  $t \in T$ , it is not the case that  $S^+ t t$  [2].

A *tree model* is a Kripke model  $(W, w_0, R, \pi)$ , with  $\mathcal{A} = \{1\}$ , where  $(W, R)$  is a tree and  $w_0$  is its root. A *tree-like model* for  $K_n$  is a model  $(W, w_0, R_1, \dots, R_n, \pi)$ , with  $\mathcal{A} = \{1, \dots, n\}$ , such that  $(W, \cup_{i \in \mathcal{A}} R_i)$  is a tree, with  $w_0$  as the root.

Let  $\mathfrak{M} = (W, w_0, R_1, \dots, R_n, \pi)$  be a tree-like model for  $K_n$ . We define the *depth* :  $W \rightarrow \mathbb{N}$  of a world  $w \in W$ , as the length of the path from  $w_0$  to  $w$  through the union of the relations in  $\mathfrak{M}$ . We sometimes say *depth* of  $\mathfrak{M}$  to mean the longest path from the root to any world in  $W$ .

The following theorems have been adapted from the ones presented in [2].

**Theorem 2.2.1.** *Let  $\varphi \in \text{WFF}_{K_n}$  be a formula and  $\mathfrak{M} = (W, w_0, R_1, \dots, R_n, \pi)$  be a model. Then  $\mathfrak{M} \models_L \varphi$  if and only if there is a tree-like model  $\mathfrak{M}'$  such that  $\mathfrak{M}' \models_L \varphi$ . Moreover,  $\mathfrak{M}'$  is finite and its depth is bounded by  $mdepth(\varphi)$ .*

The proof of Theorem 2.2.1 presented in [12] constructs a tree-like model  $\mathfrak{M}'$  as a *generated submodel* of  $\mathfrak{M}$ , that is, it restricts the binary relations to consider only a subset of  $W$ . Then, using the satisfiability invariance of generated submodels, also proved in [12], which states that a formula is satisfiable in a model if, and only if, is satisfiable in its generated submodels, the proof becomes trivial.

**Theorem 2.2.2.** *Let  $\varphi, \varphi' \in \text{WFF}_{K_n}$  and  $\mathfrak{M} = (W, w_0, R_1, \dots, R_n, \pi)$  be a tree-like model such that  $\mathfrak{M} \models_L \varphi$ . If  $(\varphi', \lambda', ml) \in \tau(\varphi, 1, 0)$  and  $\varphi'$  is satisfied in  $\mathfrak{M}$ , then there is  $w \in W$ , with  $depth(w) = ml$ , such that  $\langle \mathfrak{M}, w \rangle \models \varphi'$ . Moreover, the subtree rooted at  $w$  has height equal to  $mdepth(\varphi')$ .*

The proof of Theorem 2.2.2 is by induction on the structure of the formula and shows that a subformula  $\varphi'$  of  $\varphi$  is satisfied at a node with distance  $ml$  of the root of the tree-like model. As determining the satisfiability of a formula  $\varphi$  depends only on its subformulae  $\varphi'$ , only the subtrees of height  $mdepth(\varphi')$  starting at level  $ml$  need to be checked. The bound on the height of the subtrees follows from Theorem 2.2.1 [45].

The *local satisfiability problem* for  $K_n$  corresponds to determining the existence of a model in which a formula is locally satisfied, while the *global satisfiability problem* corresponds to determining the existence of a model in which a formula is globally satisfied. These problems are proven to be PSPACE-complete [56], for local satisfiability, and EXPTIME, for global satisfiability [56].

The global satisfiability problem for a modal logic is equivalent to the local satisfiability problem of the logic obtained by adding the universal modality,  $\Box$ , to the original modal language [30]. Let  $K_n^*$  be the logic obtained by adding  $\Box$  to  $K_n$ . A model  $\mathfrak{M}^*$  for  $K_n^*$  is the pair  $(\mathfrak{M}, R_*)$ , where  $\mathfrak{M} = (W, w_0, R_1, \dots, R_n, \pi)$  is a tree-like model for  $K_n$  and  $R_* = W \times W$ . A formula  $\Box\varphi$  is satisfied at the world  $w \in W$ , in the model  $\mathfrak{M}^*$ , written  $\langle \mathfrak{M}^*, w \rangle \models \Box\varphi$ , if, and only if, for all  $w'$  such that  $(w, w') \in R_*$ , we have that  $\langle \mathfrak{M}^*, w' \rangle \models \varphi$ . As the relation  $R_*$  is total, it is easy to see that this corresponds to the global satisfiability problem as defined before. In [30], the following result is established:  $\mathfrak{M} \models_G \varphi$ , if, and only if,  $\mathfrak{M}^* \models_L \Box\varphi$ , for a formula  $\varphi$ .

## 2.3 Proof Systems and Normal Forms

The *proof* of theorems, or the *deduction* of consequences from assumptions, in Mathematics, is typically characterized by an argument that follows from a (possibly empty) set of premises [37].

Formally, a proof is a finite object constructed according to a fixed set of syntactic rules that refer only to the structure of formulae and not to their intended meaning [25]. The set of syntactic rules that define proofs are said to specify a *proof system* or *calculus*. These rules allow the derivation of formulae from sets of formulae through strict symbol manipulation [23]. A proof system for a particular logic is *sound* if any formula that has a proof is a valid formula of the logic, and it is *complete* for a particular logic if any valid formula has a proof [25]. Therefore, a sound and complete calculus allows us to produce proofs only from formulae which are valid.

There are many kinds of proof systems. They can be loosely divide into two broad categories: *synthetic* and *analytic* [25]. “An analytic proof system decomposes the formula being proved into simpler and simpler parts. A synthetic proof system, on the other hand, builds its way up to the formula being proved. Analytic proof systems tend to be easier to use, since the field of play is sharply limited to the formula being proved” [25].

The most common example of synthetic calculus is an *axiomatic system*. Certain formulae are taken as axioms. A proof starts with these axioms and, using inference rules that produce new formulae, builds up a sequence that finally ends with the formula being proved.

*Tableau systems* are one of the more common analytic proof systems. These are *refutational systems*, i.e., to prove a formula, we begin by negating it, then analysing the entailment of doing so. If it is the case that all the consequences turn out to be impossible, we conclude that the original formula has been proved [25]. There are many varieties of tableaux, and the interesting thing about these systems is that, usually, proofs can be represented by trees of formulae, instead of sequences as mentioned above.

Another way of categorizing proof systems involves the chaining in which the rules are applied to form a line of reasoning. If the chaining starts from a set of conditions and moves toward some (possibly remote) conclusion, the system is called *forward chaining*. Backward systems, in essence, start from what is needed to be proved and moves towards the axioms.

Backward chaining is a standard technique in automated deduction, often taking the form of a version of Robinson’s *resolution rule* [36]. Calculi based on this rule is often referred as *resolution-based systems*. The fundamental question is to determine whether or not a given formula follows from a given set of formulae, and there are various techniques which can be applied to guide the search for a proof. Resolution systems for propositional

logic perform this search by thoroughly applying a single rule, with the goal of obtaining a contradiction, since it is also a refutational system. This one rule is showed in Chapter 3, where we briefly introduce the resolution system.

In the literature, there are several kinds of proof systems proposed for  $K_n$ . The one we will follow in this work is based on resolution, as proposed by [45], and it is also presented in Chapter 3. The calculus used is proved to be sound and complete for  $K_n$  in [45], it was developed with special concerning towards computer implementations and it uses formulae translated into a special *normal form*.

A normal form is an elegant representation of an equivalence class and the equivalence relation in question may determine what kind of normal form is used [35]. The relation considered in proof systems for logic languages relates two formulae if whenever one is satisfiable, the other one also is. Therefore, the transformation rules defined for a specific normal form used in a proof system for a logic must preserve satisfiability, that is, the formula obtained by applying a transformation rule is satisfiable if, and only if, the original one also is.

Formulae translated into a normal form have a specific, normalized structure, possibly resulting in less operators to handle with, which may imply in a smaller number of rules for a proof system. Hence, a calculus that is planned to be implemented in a computer may take great advantage of normal forms, since the smaller number of inference rules reduces the chances of implementation errors, for example.

The normal form used in this work is a layered normal form called Separated Normal Form with Modal Levels, originally proposed in [44]. This normal form is introduced in Chapter 3, as well as the translation rules for formulae in  $K_n$ . The proof that this translation preserves satisfiability can be found in [44].

# Chapter 3

## Modal-Layered Resolution

Resolution appeared in the early 1960's through investigations on performance improvements of refutational systems based on the *Herbrand's Theorem*, which allows a kind of reduction of first-order logic to propositional logic [14]. In particular, Prawitz' studies of such systems brought back the concept of unification. J. A. Robinson incorporated this concept on a refutational system, creating what was later known as resolution [49].

Resolution relies on saturation. The key aspect behind saturation is that information is added to the clause set until no new information can be produced.

Numerous resolution systems for propositional logic have been proposed in the literature [8]. The standard system has only one inference rule [49], showed in Equation 3.1, that takes two *clauses* with literals that form a complementary pair and generates a *resolvent*, where each clause, denoted by  $\mathcal{C}$ , is a disjunction of literals.

$$[\text{RES}] \quad \frac{\mathcal{C}_i \vee l \quad \neg l \vee \mathcal{C}_j}{\mathcal{C}_i \vee \mathcal{C}_j} \quad (3.1)$$

where  $\mathcal{C}_i$  and  $\mathcal{C}_j$  are (possibly empty) clauses,  $l$  is a literal and  $\mathcal{C}_i \vee \mathcal{C}_j$  is the resolvent.

We use the constant **false** to denote the *empty clause*, i.e., the clause that contains no literals. Due to the associativity and commutativity properties of disjunction, one may see a clause as a set of literals. In this work we might abuse of set notation, writing  $l \in \mathcal{C}$ , when  $l$  is a literal of  $\mathcal{C}$ , and  $\mathcal{C}_i \subseteq \mathcal{C}_j$ , when all literals in  $\mathcal{C}_i$  are also literals in  $\mathcal{C}_j$ .

A clause set is said to be *saturated* when further relevant information cannot be generated, regardless of the rule (or set of rules) that is applied [21]. Saturation, up to redundancy, of the initial clause set is a quite useful criteria when we are thinking in terms of termination proof and completeness proof [25] of a calculus.

Most of the systems based on the inference rule give in Equation 3.1 work exclusively with clauses in a specific normal form. Resolution, as proposed by Robinson, is a refutationally complete theorem proving method for first order logic [49]. Therefore, to show

that a formula  $\varphi$  is valid,  $\neg\varphi$  is translated into a normal form, then the inference rule is applied until either no new resolvents can be generated or a contradiction is obtained. This means that the search for a contradiction proceeds by exhaustively applying the inference rule to the clause set [8]. The contradiction implies that  $\neg\varphi$  is unsatisfiable and hence, that  $\varphi$  is valid.

Resolution-based provers are widely implemented and tested [8]. Besides reliable implementations, we can also profit from several complete strategies, as, for instance, *linear resolution* [14], *set of support strategy* [59], *ordered resolution* and *selection-based resolution* [20], or *tree-like resolution* [29]. Provers for multimodal logics require pruning of the search space for a proof in order to deal with the inherent intractability of the satisfiability problem for such logics. In [45], Nalon et. al. present a clausal modal-layered resolution calculus for  $K_n$ , which divides the clause set according to the modal layer at which each clause occurs. This calculus is introduced in Section 3.2.

### 3.1 Clausal Resolution

Clausal resolution is a simple and adaptable proof system for classical logics. It was proposed by Robinson in 1965 [49], and it was claimed to be suitable to be performed by a computer, as, for propositional logic, it has only one inference rule that is applied to the set of clauses. Robinson emphasizes that, from the theoretical point of view, an inference rule need only to be sound and effective, that is, it allows only logical consequences of premisses to be deduced and it must be algorithmically decidable whether an alleged application of the rule is indeed an application of it.

The single inference rule of this system of logic, given in Equation 3.1, entails the *resolution principle*, namely: *From any two clauses  $\mathcal{C}_i$  and  $\mathcal{C}_j$  which contain a complementary pair of literals, one may infer a resolvent of  $\mathcal{C}_i$  and  $\mathcal{C}_j$*  [49].

In his paper, Robinson presents a formalization of the calculus for first-order logic, designed to be used as the basic theoretical instrument of the proposed computer theorem-proving program. For the purpose of this work, we are only interested in the calculus for propositional logic. Therefore, we will neither discuss the theory behind the Herbrand's Theorem nor the definition of the unification procedure, but, if curious, the reader can refer to [49] for more details.

In the sense of this last remark, the only representational formalism needed is propositional logic. As resolution has only the RES rule, shown in Equation 3.1, a proof consists of repeated applications of this rule to the propositional clauses. These applications are sufficient to derive the empty clause if and only if the initial formula is unsatisfiable [29].

**Example 3.** Consider the set of clauses  $\mathcal{K} = \{(\neg p \vee q), (\neg p \vee r), (\neg r \vee q), (\neg q \vee r), \neg r, p\}$ .

1.	$\neg p \vee q$		
2.	$\neg p \vee r$		
3.	$\neg r \vee q$		
4.	$\neg q \vee r$		
5.	$\neg r$		
6.	$p$		
7.	$\neg p \vee q$	[RES,3,2]	= 1
8.	$\neg p \vee r$	[RES,4,1]	= 2
9.	$\neg q \vee q$	[RES,4,3]	= <b>true</b>
10.	$\neg r \vee r$	[RES,4,3]	= <b>true</b>
11.	$\neg p$	[RES,5,2]	
12.	$\neg q$	[RES,5,4]	
13.	$q$	[RES,6,1]	
14.	$r$	[RES,6,2]	
15.	<b>false</b>	[RES,11,6]	contradiction

Figure 3.1: Derivation of  $\mathcal{K}$  in Example 3

Figure 3.1, taken from [43], shows an example of derivation of the empty clause for  $\mathcal{K}$ , proving that this set is unsatisfiable.

Despite its simplicity, unrestricted resolution is hard to implement efficiently due to the difficulty of finding good choices of clauses to resolve [29]. As one can infer from this example, a raw implementation of resolution-based systems typically implies huge storage requirements. Even with such a short set of clauses (only 6 initially), the application of the resolution rule, without any restriction, yields the generation of tautologies, Clauses 9 and 10, and repeated clauses, Clauses 7 and 8. That is, useless information is generated and stored until the contradiction can be found.

Robinson established two principles, namely *purity principle* and *subsumption principle*, to discuss the question of developing efficient resolution systems. Such principles are called *search principles*. A third search principle is presented in terms of replacement using the subsumption principle, named, *replacement principle*.

**Definition 7** If  $\mathcal{K}$  is any finite set of clauses,  $\mathcal{C}$  is a clause in  $\mathcal{K}$  and  $l$  a literal in  $\mathcal{C}$  with the property that no literal in any other clause in  $\mathcal{K}$  form a complementary pair with  $l$ , then  $l$  is said to be *pure* in  $\mathcal{K}$ .

The purity principle is then based on Theorem 3.1.1.

**Theorem 3.1.1.** *If  $\mathcal{K}$  is any finite set of clauses, and  $l \in \mathcal{C} \in \mathcal{K}$  is a pure literal in  $\mathcal{K}$ , then  $\mathcal{K}$  is satisfiable if and only if  $\mathcal{K} - \{\mathcal{C}\}$  is satisfiable.*

**Definition 8** If  $\mathcal{C}_i$  and  $\mathcal{C}_j$  are two distinct nonempty clauses, we say that  $\mathcal{C}_i$  *subsumes*  $\mathcal{C}_j$  in the case that  $\mathcal{C}_i \subseteq \mathcal{C}_j$ .

Theorem 3.1.2 establishes the basic property of subsumption.

**Theorem 3.1.2.** *If  $\mathcal{K}$  is any finite set of clauses, and  $\mathcal{C}_j$  is any clause in  $\mathcal{K}$  which is subsumed by some clause in  $\mathcal{K} - \{\mathcal{C}_j\}$ , then  $\mathcal{K}$  is satisfiable if and only if  $\mathcal{K} - \{\mathcal{C}_j\}$  is satisfiable.*

Theorems 3.1.1 and 3.1.2 are both proved in [49].

“A particularly useful application of the subsumption principle is the following: suppose a resolvent  $\mathcal{C}_R$  of  $\mathcal{C}_i$  and  $\mathcal{C}_j$  subsumes  $\mathcal{C}_i$ , then in adding  $\mathcal{C}_R$  as a result of resolving  $\mathcal{C}_i$  and  $\mathcal{C}_j$ , we may simultaneously delete, by the subsumption principle,  $\mathcal{C}_i$ . This combined operation entails the replacement of  $\mathcal{C}_i$  by  $\mathcal{C}_R$ ; accordingly this third principle is named as the replacement principle” [49].

“The application, to a finite set  $\mathcal{K}$  of clauses, of any of the three search principles described, produces a set  $\mathcal{K}'$  which either has fewer clauses than  $\mathcal{K}$  or has the same number, but with one or more shorter clauses. An obvious method of exploiting these principles in a refutation procedure is therefore never to apply the resolution principle, generating new clauses, except to a set to which the three principles are no longer applicable.” [49]

**Example 4.** Let  $\mathcal{K}$  be the set of clauses showed in Figure 3.2a. Prior to the thorough application of the RES rule, one may search for opportunities to apply the search principles, in order to reduce the number and size of clauses.

In this example, the third clause can be eliminated from the set of clauses through an application of the purity principle, as expressed in Figure 3.2b, because there is no other clause that has the complementary pair of the literal  $u$ . Furthermore, as the Clause 5 subsumes the Clause 4, this last one can also be eliminated from the set of clauses, leaving only the clauses in Figure 3.2c. The application of RES to Clauses 1 and 2 generates the resolvent  $\neg q$ , which subsumes both clauses, hence, by the replacement principle, both may be replaced by Clause 7, as showed in Figure 3.2d. Finally, the application of RES to Clauses 5 and 7, generates the Clause 8 as a resolvent, and then resolving this one with the Clause 6 will generate the empty clause, a contradiction.

Applying the search principles, proposed by Robinson, allowed us to go from a set of six clauses with four literals to a set of four clauses with only two literals.

Further on this work, we see a practical application of these principles, but we refer as pure literal elimination and unit propagation, the purity principle and the replacement principle, respectively. There are further principles of the same general sort, possibly less

(a) Initial clauses	(b) Purity principle	(c) Subsumption	(d) Replacement
1. $\neg q \vee \neg r$	1. $\neg q \vee \neg r$	1. $\neg q \vee \neg r$	5. $\neg p \vee q$
2. $\neg q \vee r$	2. $\neg q \vee r$	2. $\neg q \vee r$	6. $p$
3. $u \vee \neg p$	4. $\neg p \vee q \vee \neg r$	5. $\neg p \vee q$	7. $\neg q$ [RES,1,2]
4. $\neg p \vee q \vee \neg r$	5. $\neg p \vee q$	6. $p$	8. $\neg p$ [RES,5,7]
5. $\neg p \vee q$	6. $p$		9. <b>false</b> [RES,6,8]
6. $p$			

Figure 3.2: Derivation schemes for Example 4

simple than the ones presented earlier, which Robinson considers to be merely a brief view of the possible approaches to the efficiency problem of resolution systems. Details can be found in [49].

## 3.2 Modal-Layered Resolution Calculus for $K_n$

The calculus presented in this section requires a translation into a more expressive modal language, presented in Section 3.2.1, where labels are used to express semantic properties of a formula. This calculus uses labelled resolution in order to avoid unnecessary applications of the inference rules [45]. For instance, we do not apply resolution to clauses at different modal levels, since they are not, in fact, contradictory.

### 3.2.1 Separated Normal Form with Modal Levels

Formulae in  $K_n$  can be transformed into a layered normal form called *Separated Normal Form with Modal Levels*, denoted by  $\text{SNF}_{ml}$ , proposed in [44], hence, all the definitions in this section are taken from [44]. A formula in  $\text{SNF}_{ml}$  is a conjunction of *clauses* where the modal level in which they occur is made explicit in the syntax as a label.

We write  $ml : \varphi$  to denote that  $\varphi$  occurs at modal level  $ml \in \mathbb{N} \cup \{*\}$ . By  $* : \varphi$  we mean that  $\varphi$  is true at all modal levels. Formally, let  $\text{WFF}_{K_n}^{ml}$  denote the set of formulae with the modal level annotation,  $ml : \varphi$ , such that  $ml \in \mathbb{N} \cup \{*\}$  and  $\varphi \in \text{WFF}_{K_n}$ . Let  $\mathfrak{M}^* = (W, w_0, R_1, \dots, R_n, R_*, \pi)$  be a tree-like model and take  $\varphi \in \text{WFF}_{K_n}$ .

**Definition 9** Satisfiability of labelled formulae is given by:

1.  $\mathfrak{M}^* \models_L ml : \varphi$  if, and only if, for all worlds  $w \in W$  such that  $\text{depth}(w) = ml$ , we have  $\langle \mathfrak{M}^*, w \rangle \models \varphi$ ;
2.  $\mathfrak{M}^* \models_L * : \varphi$  if, and only if,  $\mathfrak{M}^* \models \Box \varphi$ .

Clauses in  $\text{SNF}_{ml}$  are defined as follows.

**Definition 10** Clauses in  $\text{SNF}_{ml}$  are in one of the following forms:

1. Literal clause  $ml : \bigvee_{b=1}^r l_b$
2. Positive  $a$ -clause  $ml : l' \Rightarrow \boxed{a}l$
3. Negative  $a$ -clause  $ml : l' \Rightarrow \diamond l$

where  $r, b \in \mathbb{N}$ ,  $ml \in \mathbb{N} \cup \{*\}$ ,  $l, l', l_b \in \mathcal{L}$  and  $a \in \mathcal{A} = \{1, \dots, n\}$ .

Positive and negative  $a$ -clauses are together known as *modal  $a$ -clauses*. The index  $a$  can be omitted if it is clear from the context.

The transformation of a formula  $\varphi \in \text{WFF}_{K_n}$  into  $\text{SNF}_{ml}$  is achieved by first transforming  $\varphi$  into its *Negation Normal Form*, and then, recursively applying rewriting and renaming [47].

**Definition 11** Let  $\varphi \in \text{WFF}_{K_n}$ . We say that  $\varphi$  is in Negation Normal Form (NNF) if it contains only the operators  $\neg, \vee, \wedge, \boxed{a}$  and  $\diamond$ . Also, only propositions are allowed in the scope of negations.

Let  $\varphi$  be a formula and  $t$  a propositional symbol not occurring in  $\varphi$ . The translation of  $\varphi$  is given by  $0 : t \wedge \rho(0 : t \Rightarrow \varphi)$  — for global satisfiability, the translation is given by  $* : t \wedge \rho(* : t \Rightarrow \varphi)$  — where  $\rho$  is the *translation function* defined below. We refer as *initial clauses* the literals clauses at the modal level 0.

**Definition 12** The translation function  $\rho : \text{WFF}_{K_n}^{ml} \longrightarrow \text{WFF}_{K_n}^{ml}$  is defined as follows:

$$\begin{aligned}
\rho(ml : t \Rightarrow \varphi \wedge \psi) &= \rho(ml : t \Rightarrow \varphi) \wedge \rho(ml : t \Rightarrow \psi) \\
\rho(ml : t \Rightarrow \boxed{a}\varphi) &= (ml : t \Rightarrow \boxed{a}\varphi), \text{ if } \varphi \text{ is a literal} \\
&= (ml : t \Rightarrow \boxed{a}t') \wedge \rho(ml + 1 : t' \Rightarrow \varphi), \text{ otherwise} \\
\rho(ml : t \Rightarrow \diamond\varphi) &= (ml : t \Rightarrow \diamond\varphi), \text{ if } \varphi \text{ is a literal} \\
&= (ml : t \Rightarrow \diamond t') \wedge \rho(ml + 1 : t' \Rightarrow \varphi), \text{ otherwise} \\
\rho(ml : t \Rightarrow \varphi \vee \psi) &= (ml : \neg t \vee \varphi \vee \psi), \text{ if } \psi \text{ is a disjunction of literals} \\
&= \rho(ml : t \Rightarrow \varphi \vee t') \wedge \rho(ml : t' \Rightarrow \psi), \text{ otherwise}
\end{aligned}$$

Where  $t, t' \in \mathcal{L}$ ,  $\varphi, \psi \in \text{WFF}_{K_n}$ ,  $ml \in \mathbb{N} \cup \{*\}$  and  $r, b \in \mathbb{N}$ .

As the conjunction operator is commutative, associative and idempotent, we will commonly refer to a formula in  $\text{SNF}_{ml}$  as a set of clauses.

**Example 5.** Let  $\varphi$  be the formula  $\Box(a \Rightarrow b) \Rightarrow (\Box a \Rightarrow \Box b)$ . We show how to translate  $\varphi$  into its normal form, considering the local satisfiability problem.

First, we anchor the NNF of  $\varphi$  to the initial state:

$$0 : t_0 \wedge \rho(0 : t_0 \Rightarrow \Diamond(a \wedge \neg b) \vee \Diamond \neg a \vee \Box b) \quad (3.2)$$

The Equation 3.2 is used to anchor the meaning of  $\varphi$  to the initial state, where the formula is evaluated. The function  $\rho$  proceeds with the translation, replacing complex formulae inside the scope of the  $\Box$  and  $\Diamond$  operators, by means of renaming.

So the translation proceeds as follows:

$$\begin{aligned} & \rho(0 : t_0 \Rightarrow \Diamond(a \wedge \neg b) \vee \Diamond \neg a \vee \Box b) \\ &= \rho(0 : t_0 \Rightarrow \Diamond(a \wedge \neg b) \vee t_1) \wedge \rho(0 : t_1 \Rightarrow \Diamond \neg a \vee \Box b) \\ &= \rho(0 : t_0 \Rightarrow t_2 \vee t_1) \wedge \rho(0 : t_2 \Rightarrow \Diamond(a \wedge \neg b)) \wedge \rho(0 : t_1 \Rightarrow \Diamond \neg a \vee t_3) \wedge \rho(0 : t_3 \Rightarrow \Box b) \\ &= (0 : \neg t_0 \vee t_2 \vee t_1) \wedge (0 : t_2 \Rightarrow \Diamond t_4) \wedge \rho(1 : t_4 \Rightarrow a \wedge \neg b) \wedge \rho(0 : t_1 \Rightarrow t_5 \vee t_3) \wedge \\ & \quad (0 : t_5 \Rightarrow \Diamond \neg a) \wedge (0 : t_3 \Rightarrow \Box b) \\ &= (0 : \neg t_0 \vee t_2 \vee t_1) \wedge (0 : t_2 \Rightarrow \Diamond t_4) \wedge \rho(1 : t_4 \Rightarrow a) \wedge \rho(1 : t_4 \Rightarrow \neg b) \wedge \\ & \quad (0 : \neg t_1 \vee t_5 \vee t_3) \wedge (0 : t_5 \Rightarrow \Diamond \neg a) \wedge (0 : t_3 \Rightarrow \Box b) \\ &= (0 : \neg t_0 \vee t_2 \vee t_1) \wedge (0 : t_2 \Rightarrow \Diamond t_4) \wedge (1 : \neg t_4 \vee a) \wedge (1 : \neg t_4 \vee \neg b) \wedge \\ & \quad (0 : \neg t_1 \vee t_5 \vee t_3) \wedge (0 : t_5 \Rightarrow \Diamond \neg a) \wedge (0 : t_3 \Rightarrow \Box b) \end{aligned}$$

The translation generates eight clauses, two of them at the subsequent modal level ( $1 : \neg t_4 \vee a$  and  $1 : \neg t_4 \vee \neg b$ ). Note that, from the six clauses at the initial modal level, we have three literal clauses ( $0 : t_0$ ,  $0 : \neg t_0 \vee t_2 \vee t_1$  and  $0 : \neg t_1 \vee t_5 \vee t_3$ ), known as the initial clauses, two negative clauses ( $0 : t_2 \Rightarrow \Diamond t_4$  and  $0 : t_5 \Rightarrow \Diamond \neg a$ ) and one positive clause ( $0 : t_3 \Rightarrow \Box b$ ).

The set of clauses obtained by translating the formula  $\varphi$  into  $\text{SNF}_{ml}$ , from Example 5, is locally satisfiable if, and only if,  $\varphi$  is locally satisfiable, as given by the next lemma, taken from [45].

**Lemma 3.2.1.** *Let  $\varphi \in \text{WFF}_{K_n}$  be a formula and let  $t$  be a propositional symbol not occurring in  $\varphi$ . Then:*

- (i)  *$\varphi$  is locally satisfiable if, and only if,  $0 : t \wedge \rho(0 : t \Rightarrow \varphi)$  is satisfiable;*

(ii)  $\varphi$  is globally satisfiable if, and only if,  $* : t \wedge \rho(* : t \Rightarrow \varphi)$  is satisfiable.

### 3.2.2 Calculus

The motivation for the use of the labelled clausal normal form in a calculus is that inference rules can then be guided by the semantic information given by the labels and applied to smaller sets of clauses, reducing the number of unnecessary applications of the inference rules, and therefore improving the efficiency of the proof procedure [46].

The modal-layered resolution calculus, proposed by Nalon et. al. in [45], comprises a set of inference rules, given in Table 3.1, for dealing with propositional and modal reasoning. In the following, we denote by  $\sigma$  the result of unifying the labels in the premises for each rule. Formally, unification is given by a function  $\sigma : \mathcal{P}(\mathbb{N} \cup \{*\}) \rightarrow \mathbb{N} \cup \{*\}$ , where  $\sigma(\{ml, *\}) = ml$  and  $\sigma(\{ml\}) = ml$ ; otherwise,  $\sigma$  is undefined. The inference rules showed in Table 3.1 can only be applied if the unification of their labels is defined (where  $* - 1 = *$ ). Note that for GEN1 and GEN3, if the modal clauses occur at the modal level  $ml$ , then the literal clause occurs at the next modal level,  $ml + 1$ .

**Definition 13** Let  $\mathcal{K}$  be a set of clauses in  $\text{SNF}_{ml}$ . A *derivation* from  $\mathcal{K}$  is a sequence of sets  $\mathcal{K}_0, \mathcal{K}_1, \dots$  where  $\mathcal{K}_0 = \mathcal{K}$  and, for each  $i > 0$ ,  $\mathcal{K}_{i+1} = \mathcal{K}_i \cup \{D\}$ , where  $D$  is the resolvent obtained from  $\mathcal{K}_i$  by an application of either LRES, MRES, GEN1, GEN2 or GEN3. It is also required that  $D$  is in simplified form,  $D \notin \mathcal{K}_i$  and that  $D$  is not a tautology. A *local refutation* for  $\mathcal{K}$  is a finite derivation that contains the empty clause at the initial modal level, that is  $0 : \text{false}$ . Meanwhile, a *global refutation* for  $\mathcal{K}$  is a finite derivation that contains the empty clause at any modal level [45].

**Example 6.** Consider the set of clauses in  $\text{SNF}_{ml}$  of Example 5, generated for  $\varphi = \Box(a \Rightarrow b) \Rightarrow (\Box a \Rightarrow \Box b)$ .

Figure 3.3 shows a derivation from the eight clauses obtained by the transformation, once that no other rule can be applied and no refutation is generated. Thus, as there is no proof,  $\varphi$  is a satisfiable formula, as expected.

1. $0 : t_0$	8. $1 : \neg t_4 \vee \neg b$	
2. $0 : \neg t_0 \vee t_2 \vee t_1$	9. $0 : t_2 \vee t_1$	[LRES, 1, 2, $t_0$ ]
3. $0 : \neg t_1 \vee t_5 \vee t_3$	10. $0 : t_2 \vee t_5 \vee t_3$	[LRES, 9, 3, $t_1$ ]
4. $0 : t_2 \Rightarrow \Diamond t_4$	11. $0 : \neg t_2$	[GEN1, 4, 7, 8, $t_4$ ]
5. $0 : t_5 \Rightarrow \Diamond \neg a$	12. $0 : t_5 \vee t_3$	[LRES, 10, 11, $t_2$ ]
6. $0 : t_3 \Rightarrow \Box b$	13. $0 : \neg t_3$	[GEN3, 6, 5, 8, $b, a$ ]
7. $1 : \neg t_4 \vee a$	14. $0 : t_5$	[LRES, 13, 14, $t_3$ ]

Figure 3.3: Satisfiability proof of the formula  $\varphi$  from Example 5

Table 3.1: Inference rules

$\text{[LRES]} \quad \frac{ml_1 : D \vee l \quad ml_2 : D' \vee \neg l}{\sigma(\{ml_1, ml_2\}) : D \vee D'}$	$\text{[MRES]} \quad \frac{ml_1 : l_1 \Rightarrow \boxed{a}l \quad ml_2 : l_2 \Rightarrow \neg \boxed{a}l}{\sigma(\{ml_1, ml_2\}) : \neg l_1 \vee \neg l_2}$
$\text{[GEN2]} \quad \frac{ml_1 : l'_1 \Rightarrow \boxed{a}l_1 \quad ml_2 : l'_2 \Rightarrow \boxed{a}\neg l_1 \quad ml_3 : l'_3 \Rightarrow \boxed{a}l_2}{\sigma(\{ml_1, ml_2, ml_3\}) : \neg l'_1 \vee \neg l'_2 \vee \neg l'_3}$	
$\text{[GEN1]} \quad \frac{ml_1 : l'_1 \Rightarrow \boxed{a}\neg l_1 \quad \vdots \quad ml_m : l'_m \Rightarrow \boxed{a}\neg l_m \quad ml_{m+1} : l' \Rightarrow \boxed{a}l \quad ml_{m+2} : l_1 \vee \dots \vee l_m \vee l}{ml : \neg l'_1 \vee \dots \vee \neg l'_m \vee \neg l'}$	$\text{[GEN3]} \quad \frac{ml_1 : l'_1 \Rightarrow \boxed{a}\neg l_1 \quad \vdots \quad ml_m : l'_m \Rightarrow \boxed{a}\neg l_m \quad ml_{m+1} : l' \Rightarrow \boxed{a}l \quad ml_{m+2} : l_1 \vee \dots \vee l_m}{ml : \neg l'_1 \vee \dots \vee \neg l'_m \vee \neg l'}$
<p>where <math>ml = \sigma(\{ml_1, \dots, ml_{m+1}, ml_{m+2} - 1\})</math></p>	<p>where <math>ml = \sigma(\{ml_1, \dots, ml_{m+1}, ml_{m+2} - 1\})</math></p>

**Example 7.** Adapted from [1, 45]. Consider the clauses in Figure 3.4. Clauses 1 and 2 state that a dog is either male or female. Clauses 3 and 4, only serving the purpose of illustration, say that big dogs have puppies with brown fur. The particular situation of Toto, denoted here by  $t_0$ , is given in the following clauses: Clauses 5, 6 and 7 say that Toto's puppies are all female and big. Clauses 8 and 9 say that a grandpuppy of Toto does not have brown fur. We want to prove that Toto has a male puppy, which appears negated in Clause 10. The refutation is given in Figure 3.4.

1. $* : female \vee male$	9. $1 : t_3 \Rightarrow \boxed{a}\neg brown$	
2. $* : \neg female \vee \neg male$	10. $0 : t_0 \Rightarrow \boxed{p}\neg male$	
3. $* : \neg big \vee t_1$	11. $1 : \neg t_1 \vee \neg t_3$	[MRES, 9, 4, <i>brown</i> ]
4. $* : t_1 \Rightarrow \boxed{p} brown$	12. $1 : \neg big \vee \neg t_3$	[LRES, 11, 3, $t_1$ ]
5. $0 : t_0$	13. $1 : \neg t_3 \vee \neg t_2 \vee \neg female$	[LRES, 7, 12, <i>big</i> ]
6. $0 : t_0 \Rightarrow \boxed{p} t_2$	14. $1 : male \vee \neg t_3 \vee \neg t_2$	[LRES, 13, 1, <i>big</i> ]
7. $1 : \neg t_2 \vee \neg female \vee big$	15. $0 : \neg t_0$	[GEN1, 10, 6, 8, 14, <i>male, t_2, t_3</i> ]
8. $0 : t_0 \Rightarrow \boxed{a} t_3$	16. $0 : \mathbf{false}$	[LRES, 15, 5, $t_0$ ]

Figure 3.4: An example of refutation

The proofs for termination, soundness and completeness of this calculus can be found in [45].

### 3.2.3 K<sub>S</sub>P

In this section, we briefly introduce K<sub>S</sub>P, the theorem prover presented in [46] for the basic multimodal logic  $K_n$ , which implements a variation of the set of support strategy [59] for the modal resolution-based calculus described in Section 3.2.

KSP was designed to support experimentation with different combinations of refinements of its basic calculus. Refinements and options for processing and preprocessing the input are coded as independently as possible in order to allow for the easy addition and testing of new features. Although this may not lead to optimal performance, since techniques need to be applied one after another, whereas most tools would apply them all together, it might help evaluating how the different options independently contribute to achieve efficiency [46].

The results showed in [46] indicate that KSP works well on problems with high modal depth where the separation of modal layers can be exploited to improve the efficiency of reasoning. Although, as with all provers that provide a variety of strategies and optimizations, to get the best performance for a particular formula or class or formulae, it is important to choose the right strategy and optimizations. KSP leaves this choice to the user. The same applies to the transformation to the layered normal form.

According to [46], KSP performs well if the set of propositional symbols are uniformly distributed over the modal levels. However, when there is a high number of propositional symbols in just one particular level, the performance deteriorates. One reason is that the specific normal form we use always generates satisfiable sets of propositional clauses. As resolution relies on saturation, this can be very time consuming. We are currently investigating the use of other tools in order to speed up the saturation process.

In the next chapter we present some clever techniques proposed to deal with propositional reasoning. These techniques lead to efficient implementations of SAT solvers, which determine whether a propositional formula is satisfiable or not. We believe that this kind of solver may be useful to speed up the time KSP spends dealing with propositional logic.

# Chapter 4

## Satisfiability Solvers

The problem of determining whether a formula in classical propositional logic is satisfiable has the historical honor of being the first problem ever shown to be NP-Complete [17]. Great efforts have been directed in improving the efficiency of solvers for this problem, known as *Boolean Satisfiability Solvers*, or just *SAT solvers*. Despite the worst-case deterministic exponential run time of all the algorithms known, satisfiability solvers are increasingly leaving their mark as a general purpose tool in the most diverse areas [29]. In essence, SAT solvers provide a generic combinatorial reasoning and search platform for such problems. Beyond that, the source code of many implementations of such solvers is freely available and can be used as a basis for the development of decision procedures for more expressive logics [28].

In the context of SAT solvers for propositional provers, the underlying representation formalism is propositional logic [29]. We are interested in formulae in *Conjunctive Normal Form* (CNF): a formula  $\varphi$  is in CNF if it is a conjunction of clauses. For example,  $\varphi = (p \vee \neg q) \wedge (\neg p \vee r \vee s) \wedge (q \vee r)$  is a CNF formula with four variables and three clauses. A clause with only one literal is referred to as a *unit clause*, and a clause with two literals, as a *binary clause*.

A propositional formula  $\varphi$  takes a value in the set  $\{false, true\}$ . In algorithms for SAT, variables can be *assigned* a logical value in this same set and, alternatively, variables may also be *unassigned*. A *truth assignment* (or just an assignment) to the set of variables  $\mathcal{P}$ , is the valuation function  $\pi$  as defined in Definition 5. As in propositional logic we have a unit set as the set of possible worlds  $W$ , we can omit this set from the function signature and just write  $\pi : \mathcal{P} \longrightarrow \{false, true\}$ , for simplicity. A *satisfying assignment* for  $\varphi$  is an assignment  $\pi$  such that  $\varphi$  evaluates to *true* under  $\pi$ . A *partial assignment* for a formula  $\varphi$  is a truth assignment to a subset of the variables in  $\varphi$ . For a partial assignment  $\rho$  for a CNF formula  $\varphi$ ,  $\varphi|_{\rho}$  denotes the simplified formula obtained by replacing the variables appearing in  $\rho$  with their specified values, removing all clauses with at least one *true*

literal, and deleting all occurrences of *false* literals from the remaining clauses [29].

Therefore, the *Boolean Satisfiability Problem* (SAT) can be expressed as: Given a CNF formula  $\varphi$ , does  $\varphi$  have a satisfying assignment? If this is the case,  $\varphi$  is said to be *satisfiable*, otherwise,  $\varphi$  is *unsatisfiable*. One can be interested not only in the answer of this decision problem, but also in finding the actual assignment that satisfies the formula, when it exists. All practical SAT solvers do produce such an assignment [18].

## 4.1 The DPLL Procedure

A *complete* solution method for the SAT problem is one that, given the input formula  $\varphi$ , either produces a satisfying assignment for  $\varphi$  or proves that it is unsatisfiable [29]. One of the most surprising aspects of the relatively recent practical progress of SAT solvers is that the best complete methods remain variants of a process introduced in the early 1960's: the Davis-Putnam-Logemann-Loveland, or DPLL, procedure [19], which describes a backtracking algorithm to the search problem of finding a satisfying assignment for a formula in the space of partial assignments. A key feature of DPLL is the efficient pruning of the search space based on falsified clauses. Since its introduction, the main improvements to DPLL have been smart branch selection heuristics, extensions like clause learning and randomized restarts, and well-crafted data structures such as lazy implementations and watched literals for fast unit propagation [29].

Algorithm 1, DPLL-recursive( $\varphi, \rho$ ) sketches the basic DPLL procedure on CNF formulae [19], where  $\rho$  corresponds to a partial assignment of the CNF formula  $\varphi$ . The main idea is to repeatedly select an unassigned literal  $l$  in the input formula and recursively search for a satisfying assignment for  $\varphi|_l$  and  $\varphi|_{\neg l}$ . The step where such an  $l$  is chosen is called a *branching step* and  $l$  is referred as a *decision variable*. Setting the decision variable to *true* or *false* when making a recursive call is referred to as a *decision*, which is associated with a *decision level* and it is equal to the recursion depth at that stage of the procedure. The end of each recursive call, which takes  $\varphi$  back to fewer assigned literals, is called the *backtracking step*.

A partial assignment  $\rho$  is maintained during the search and it is output if the formula turns out to be satisfiable. To increase efficiency, a key procedure in SAT solvers is the *unit propagation procedure* [11], where unit clauses are immediately set to *true* as outlined in Algorithm 1. In most implementations of DPLL, logical inferences can be derived with unit propagation. Thus, this procedure is used for identifying variables which must be assigned a specific value. If  $\varphi|_\rho$  contains the empty clause, a *conflict* condition is declared, the corresponding clause of  $\varphi$  from which it came is said to be *violated* by  $\rho$ , and the algorithm backtracks.

---

**Algorithm 1:** DPLL-recursive( $\varphi, \rho$ )

---

```

1  ( $\varphi, \rho$ )  $\leftarrow$  UnitPropagate( $\varphi, \rho$ )
2  if  $\varphi$  contains the empty clause then
3  |   return UNSAT
4  end
5  if  $\varphi$  has no clauses left then
6  |   Output  $\rho$ 
7  |   return SAT
8  end
9   $l \leftarrow$  a literal not assigned by  $\rho$ 
10 if DPLL-recursive( $\varphi|_l, \rho \cup \{l\}$ ) = SAT then
11 |   return SAT
12 end
13 return DPLL-recursive( $\varphi|_{\neg l}, \rho \cup \{\neg l\}$ )

1 sub UnitPropagate( $\varphi, \rho$ )
2 |   while  $\varphi$  contains no empty clause but has a unit clause  $\mathcal{C}$  do
3 |   |    $l \leftarrow$  the literal in  $\mathcal{C}$  not assigned by  $\rho$ 
4 |   |    $\varphi \leftarrow \varphi|_l$ 
5 |   |    $\rho \leftarrow \rho \cup \{l\}$ 
6 |   end
7 |   return ( $\varphi, \rho$ )

```

---

The literals whose negation do not appear in the formula, called *pure literals*, are also set to *true* as a preprocessing step and, in some implementations, during the simplification process after every branching. We mentioned pure literal elimination in Chapter 3 as the purity principle proposed by Robinson.

Variants of the DPLL algorithm form the most widely used family of complete algorithms for the SAT problem. They are frequently implemented in an iterative manner, instead of using recursion, resulting in significantly reduced memory usage. The efficiency of state-of-the-art SAT solvers relies heavily on various features that have been developed, analysed and tested over the last two decades. These include fast unit propagation using watched literals, deterministic and randomized restart strategies, effective clause deletion mechanisms, smart static and dynamic branching heuristics and learning mechanisms. We will discuss learning mechanisms in the next section and refer the reader to [29] for more details about other search strategies.

## 4.2 Conflict-Driven Clause Learning

One of the main reasons for the widespread use of SAT in many applications is that solvers based on clause learning are effective in practice [29]. The main idea behind *Conflict-*

*Driven Clause Learning* (CDCL) is to cache “causes of conflict” as learned clauses, and utilize this information to prune the search in a different part of the search space encountered later. Since their inception in the mid-90s, CDCL SAT solvers have been applied, in many cases with remarkable success, to a number of practical applications [11]. The organization of CDCL SAT solvers is primarily inspired by the DPLL procedure. The notation used in this section is based on the one in [11].

In CDCL SAT solvers, each variable  $p$  is characterized by a number of properties. Mainly, we need to maintain its *value*, its *antecedent* and its decision level. A variable’s value is denoted by  $\nu(p)$ , and defined in the set  $\{false, true, u\}$ , where  $\nu(p) = u$  means that  $p$  is still unassigned.

A variable  $p$  that is assigned a value as the result of unit propagation is said to be *implied*. The unit clause  $\mathcal{C}$  used for implying this value is said to be the antecedent of  $p$ , and it is denoted by  $\alpha(p) = \mathcal{C}$ . For decision variables or unassigned variables, the antecedent is *nil*. Ergo, antecedents are only defined for variables whose value is implied by other assignments.

The decision level of a variable  $p$ , written  $\delta(p)$ , denotes the depth of the decision tree at which the variable is assigned a value in  $\{false, true\}$  or  $\delta(p) = -1$  if the value of  $p$  is still unassigned, therefore,  $\delta(p) \in \{-1, 0, 1, \dots, |\mathcal{P}_\varphi|\}$ , where  $\mathcal{P}_\varphi$  denotes the set of all variables that appear on the initial formula  $\varphi$ . The decision level associated with variables used for branching steps is specified by the search process, and denotes the current depth of the *decision stack*. Hence, a variable  $p$  associated with a decision assignment is characterized by having  $\alpha(p) = nil$  and  $\delta(p) > 0$ . More formally, the decision level of  $p$  with antecedent  $\mathcal{C}$  is given by:

$$\delta(p) = \max(\{0\} \cup \{\delta(p') \mid p' \in \mathcal{C} \wedge p' \neq p\}) \quad (4.1)$$

i.e. the decision of an implied literal is either the highest decision level of the implied literals in a unit clause, or it is 0 in case the clause is unit. The notation  $p = v@d$  is used to denote that  $\nu(p) = v$  and  $\delta(p) = d$ . Moreover, the decision level of a literal is defined as the decision level of its variable, that is,  $\delta(l) = \delta(p)$  if  $l = p$  or  $l = \neg p$ .

**Example 8.** Consider the formula

$$\begin{aligned} \varphi &= \mathcal{C}_1 \wedge \mathcal{C}_2 \wedge \mathcal{C}_3 \\ &= (p \vee \neg s) \wedge (p \vee r) \wedge (\neg r \vee q \vee s) \end{aligned}$$

Assume that the decision assignment is  $s = false@1$ . Unit propagation yields no additional implied assignments. Assume that the second decision is  $p = false@2$ . Unit propagation yields the implied assignments  $r = true@2$  and  $q = true@2$ . Therefore,

$\pi = \{(s, false), (p, false), (r, true), (q, true)\}$  is a satisfying assignment for  $\varphi$ , since  $\pi$  makes  $\varphi$  true. Moreover,  $\alpha(r) = \mathcal{C}_2$  and  $\alpha(q) = \mathcal{C}_3$ .

During the execution of a DPLL based SAT solver, assigned variables, as well as their antecedents, define a directed acyclic graph  $I = (V_I, E_I)$  referred to as the *implication graph* [53]. The vertices of this graph are assigned variables or the special node  $\varepsilon$ , which represents a contradiction, then  $V_I \subseteq \mathcal{P} \cup \{\varepsilon\}$ . The edges in the implication graph are obtained from the antecedent of each implied variable: if  $\alpha(p) = \mathcal{C}$  then there is a directed edge, labelled by  $\mathcal{C}$ , from each variable in  $\mathcal{C}$ , other than  $p$ , to  $p$ . If unit propagation yields an unsatisfiable clause  $\mathcal{C}_i$ , then the special vertex  $\varepsilon$ , for the empty clause, is used to represent it. In this case, the antecedent of  $\varepsilon$  is defined by  $\alpha(\varepsilon) = \mathcal{C}_i$ .

The edges of  $I$  are formally defined below.

**Definition 14** Let  $z, z_1, z_2 \in V_I$  be vertices in  $I$ , in order to derive the conditions for existence of edges in  $I$ , a number of predicates need to be defined first. The predicate  $\gamma(z, \mathcal{C})$  takes value 1 if, and only if,  $z$  is a literal in  $\mathcal{C}$ , and is defined as follows:

$$\gamma(z, \mathcal{C}) = \begin{cases} 1 & \text{if } z \in \mathcal{C} \vee \neg z \in \mathcal{C} \\ 0 & \text{otherwise} \end{cases} \quad (4.2)$$

This predicate can now be used for testing the value of a literal in  $z$  in a given clause. The predicate  $\nu_0(z, \mathcal{C})$  takes value 1 if, and only if,  $z$  is a literal in  $\mathcal{C}$  and its value is *false*:

$$\nu_0(z, \mathcal{C}) = \begin{cases} 1 & \text{if } \gamma(z, \mathcal{C}) \wedge z \in \mathcal{C} \wedge \nu(z) = false \\ 1 & \text{if } \gamma(z, \mathcal{C}) \wedge \neg z \in \mathcal{C} \wedge \nu(z) = true \\ 0 & \text{otherwise} \end{cases} \quad (4.3)$$

The predicate  $\nu_1(z, \mathcal{C})$  takes value 1 if, and only if,  $z$  is a literal in  $\mathcal{C}$  and its value is *true*:

$$\nu_1(z, \mathcal{C}) = \begin{cases} 1 & \text{if } \gamma(z, \mathcal{C}) \wedge z \in \mathcal{C} \wedge \nu(z) = true \\ 1 & \text{if } \gamma(z, \mathcal{C}) \wedge \neg z \in \mathcal{C} \wedge \nu(z) = false \\ 0 & \text{otherwise} \end{cases} \quad (4.4)$$

As a result, there is an edge from  $z_1$  to  $z_2$  in  $I$  if, and only if, the following predicate takes value 1:

$$\epsilon(z_1, z_2) = \begin{cases} 1 & \text{if } z_2 = \varepsilon \wedge \gamma(z_1, \alpha(\varepsilon)) \\ 1 & \text{if } z_2 \neq \varepsilon \wedge \alpha(z_2) = \mathcal{C} \wedge \nu_0(z_1, \mathcal{C}) \wedge \nu_1(z_2, \mathcal{C}) \\ 0 & \text{otherwise} \end{cases} \quad (4.5)$$

Figure 4.1: Implication graph for Example 9

Consequently, the set of edges  $E_I$  of the implication graph  $I$  is given by:

$$E_I = \{(z_1, z_2) \mid \epsilon(z_1, z_2) = 1\} \quad (4.6)$$

Observe that a labelling function for associating a clause with each edge can also be defined.

**Definition 15** Let  $\iota : V_I \times V_I \longrightarrow \varphi$  be a labeling function. Then  $\iota(z_1, z_2)$ , with  $z_1, z_2 \in V_I$  and  $(z_1, z_2) \in E_I$ , is defined by  $\iota(z_1, z_2) = \alpha(z_2)$ .

**Example 9.** (Implication graph without conflict). Consider the CNF formula:

$$\begin{aligned} \varphi &= \mathcal{C}_1 \wedge \mathcal{C}_2 \wedge \mathcal{C}_3 \\ &= (p \vee t \vee \neg q) \wedge (p \vee \neg r) \wedge (q \vee r \vee s) \end{aligned}$$

Assume the decision assignment  $t = \text{false@1}$  has been taken. Moreover, assume that the current decision assignment is  $p = \text{false@2}$ . Unit propagation yields the implied assignments  $q = \text{false@2}$ ,  $r = \text{false@2}$  and  $s = \text{true@2}$ . The resulting implication graph is shown in Figure 4.1. As all variables have been assigned a value and the implication graph does not contain the vertex  $\varepsilon$ , this set of decision assignments forms a satisfying assignment for  $\varphi$ .

**Example 10.** (Implication graph with conflict). Consider the CNF formula:

$$\begin{aligned} \psi &= \mathcal{C}_1 \wedge \mathcal{C}_2 \wedge \mathcal{C}_3 \wedge \mathcal{C}_4 \wedge \mathcal{C}_5 \wedge \mathcal{C}_6 \\ &= (p \vee t \vee \neg q) \wedge (p \vee \neg r) \wedge (q \vee r \vee s) \wedge (\neg s \vee \neg u) \wedge (y \vee \neg s \vee \neg x) \wedge (u \vee x) \end{aligned}$$

Figure 4.2: Implication graph for Example 10

Assume the decision assignments  $y = \text{false}@2$  and  $t = \text{false}@3$ . Moreover, assume the current decision assignment  $p = \text{false}@5$ . Unit propagation yields the implied assignments  $q = \text{false}@2$ ,  $r = \text{false}@2$ ,  $s = \text{true}@2$ ,  $u = \text{false}@5$  and  $x = \text{false}@5$ . These last two assignments generate a conflict because the clause  $\mathcal{C}_6$  can not be satisfied. Therefore, the resulting implication graph has the conflict vertex, as shown in Figure 4.2, with  $\alpha(\varepsilon) = \mathcal{C}_6$ . Hence, this set of decision assignments does not satisfy  $\psi$ .

Algorithm 2, adapted from [11], shows the standard structure of a CDCL SAT solver, which essentially follows the one from DPLL. With respect to DPLL, the main differences are the call to function **ConflictAnalysis** each time a conflict is identified, and the call to **Backtrack** when backtracking takes place. Moreover, the **Backtrack** procedure allows for backtracking non-chronologically.

In addition to the main CDCL function, the following auxiliary functions are used:

- **UnitPropagate**: same as in DPLL, consists of the iterated application of the unit propagation procedure. If an unsatisfiable clause is identified, then a conflict indication is returned.
- **AllVariablesAssigned**: tests whether all variables have been assigned, in which case the algorithm terminates indicating that the CNF formula is satisfiable.
- **PickBranchingVariable**: consists of selecting a variable to assign and deciding its value.
- **ConflictAnalysis**: consists of analysing the most recent conflict and learning a new clause from the conflict. The organization of this procedure is described in Section 4.2.1.
- **Backtrack**: backtracks to the decision level computed by **ConflictAnalysis**.

---

**Algorithm 2:** CDCL( $\varphi, \rho$ )

---

```
1 if UnitPropagate( $\varphi, \rho$ ) yields a conflict then
2   | return UNSAT
3 end
4  $dl \leftarrow 0$ 
5 while  $\neg$ AllVariablesAssigned( $\varphi, \rho$ ) do
6   |  $l \leftarrow$  PickBranchingVariable( $\varphi, \rho$ )
7   |  $dl \leftarrow dl + 1$ 
8   |  $\rho \leftarrow \rho \cup \{l\}$ 
9   | if UnitPropagate( $\varphi, \rho$ ) yields a conflict then
10    |  $\beta \leftarrow$  ConflictAnalysis(formula,  $\rho$ )
11    | if  $\beta < 0$  then
12    |   | return UNSAT
13    | end
14    | else
15    |   | Backtrack( $\varphi, \rho, \beta$ )
16    |   |  $dl \leftarrow \beta$ 
17    | end
18   | end
19 end
```

---

Arguments to the auxiliary functions are assumed to be passed by reference. Hence,  $\varphi$  and  $\rho$  are supposed to be modified during execution of these functions.

The typical CDCL algorithm, shown in Algorithm 2, does not account for a few often used techniques, as for instance, search restarts and deletion policies. Search restarts cause the algorithm to restart itself, but keeping the learnt clauses. Clause deletion policies are used to decide learnt clauses that can be deleted, which allows the memory usage of the SAT solver to be kept under control. If interested, the reader can refer to [11] and [29] for more information about these techniques.

### 4.2.1 Conflict Analysis

Each time the CDCL SAT solver identifies a conflict due to unit propagation, the conflict analysis procedure is invoked. As a result, one or more new clauses are learnt, and a backtracking decision level is computed. This procedure analyses the structure of unit propagation and decides which literals to include in the learnt clause.

The decision levels associated with assigned variables define a partial order over the variables. Starting from a given unsatisfiable clause (represented in the implication graph as the vertex  $\varepsilon$ ), the conflict analysis procedure visits variables implied at the most recent decision level. This means that this procedure will visit the graph vertex which represents the variables assigned at the current largest decision level. Then, it identifies

the antecedents of these variables and keeps from the antecedents the literals assigned at decision levels less than the one being considered. This process is repeated until the most recent decision variable is visited.

Let  $d$  be the current decision level and  $p$  the current decision variable such that  $\delta(p) = d$ . Let  $\nu(p) = v$  be the decision assignment and let  $\mathcal{C}$  be an unsatisfiable clause identified with unit propagation. In terms of the implication graph, the conflict vertex  $\varepsilon$  is such that  $\alpha(\varepsilon) = \mathcal{C}$ . Moreover, take  $\odot$  to represent the process of applying the resolution principle, that is, for two clauses  $\mathcal{C}_i$  and  $\mathcal{C}_j$  containing contradictory literals,  $\mathcal{C}_i \odot \mathcal{C}_j$  denotes the application of the resolution rule as defined by Equation 3.1. For instance, if  $l$  and  $\neg l$  are literals of  $\mathcal{C}_i$  and  $\mathcal{C}_j$ , respectively,  $\mathcal{C}_i \odot \mathcal{C}_j$  contains all the literals of both clauses with the exception of the contradictory pair.

The clause learning procedure used in SAT solvers can be defined by a sequence of selective resolution operations [9, 54], that at each step yields a *new temporary clause*.

**Definition 16** Let  $l$  be a literal of a clause  $\mathcal{C}$ , and  $d$  the current decision level. Then, consider the following predicate:

$$\xi(\mathcal{C}, l, d) = \begin{cases} 1 & \text{if } l \in \mathcal{C} \wedge \delta(l) = d \wedge \alpha(l) \neq \text{nil} \\ 0 & \text{otherwise} \end{cases} \quad (4.7)$$

Then, using the predicate defined by Equation 4.7, let  $\mathcal{C}^{d,i}$ , with  $i = 0, 1, \dots$ , be a intermediate clause obtained as follows:

$$\mathcal{C}^{d,i} = \begin{cases} \alpha(\varepsilon) & \text{if } i = 0 \\ \mathcal{C}^{d,i-1} \odot \alpha(l) & \text{if } i \neq 0 \wedge \xi(\mathcal{C}^{d,i-1}, l, d) = 1 \\ \mathcal{C}^{d,i-1} & \text{if } i \neq 0 \wedge \forall l \xi(\mathcal{C}^{d,i-1}, l, d) = 0 \end{cases} \quad (4.8)$$

The predicate  $\xi$  holds if, and only if, the implied literal  $l$  of  $\mathcal{C}$  is assigned a value at the current decision level  $d$ .

Equation 4.8 can be used for formalizing the clause learning procedure. The first condition,  $i = 0$ , denotes the initialization step given after  $\varepsilon$  is generated in  $I$ , where all literals in the unsatisfiable clause are added to the first intermediate clause. Afterwards, at each step  $i$ , a literal  $l$  assigned at the current decision level  $d$  is selected and the intermediate clause  $\mathcal{C}^{d,i-1}$  is resolved with the antecedent of  $l$ . Therefore,  $\mathcal{C}^{d,i}$  denotes the clause obtained after  $i$  resolution operations.

An iteration  $i$  such that  $\mathcal{C}^{d,i} = \mathcal{C}^{d,i-1}$  represents a reached *fixed point*, and  $\mathcal{C}_L \stackrel{\text{def}}{=} \mathcal{C}^{d,i}$  denotes the new learnt clause. Observe that the number of resolution operations

Table 4.1: Resolution steps during clause learning

$\mathcal{C}^{5,0} = \{u, x\}$	Literals in $\alpha(\varepsilon)$
$\mathcal{C}^{5,1} = \{\neg s, x\}$	Resolve with $\alpha(u) = \mathcal{C}_4$
$\mathcal{C}^{5,2} = \{\neg s, y\}$	Resolve with $\alpha(x) = \mathcal{C}_5$
$\mathcal{C}^{5,3} = \{q, r, y\}$	Resolve with $\alpha(s) = \mathcal{C}_3$
$\mathcal{C}^{5,4} = \{p, t, r, y\}$	Resolve with $\alpha(q) = \mathcal{C}_1$
$\mathcal{C}^{5,5} = \{p, t, y\}$	Resolve with $\alpha(r) = \mathcal{C}_2$
$\mathcal{C}^{5,6} = \mathcal{C}_L = \{p, t, y\}$	No more resolution operations given

represented by Equation 4.8 is no greater than  $|\mathcal{P}_\varphi|$ .

**Example 11.** (Clause learning) Consider Example 10. The application of clause learning to this example results in the intermediate clauses shown in Table 4.1. The resulting learnt clause is  $\mathcal{C}_L = \mathcal{C}^{5,6} = (p \vee t \vee y)$ . Alternatively, this clause can be obtained by inspecting the graph in Figure 4.2 and selecting the negation of the literals assigned at decision levels less than the current decision level 5, i.e.  $t = \text{false@3}$  and  $y = \text{false@2}$ , and by selecting the current decision assignment  $p = \text{false@5}$ .

Modern SAT solvers implement an additional refinement of Definition 16, by further exploiting the structure of implied assignments induced by unit propagation, which is a key aspect of the clause learning procedure [53]. This aspect was further explored with *Unit Implication Points* (UIPs) [53]. A UIP is a vertex  $u$  in the implication graph, such that every path from a decision vertex  $p$  to the conflict vertex  $\varepsilon$  contains  $u$ . It represents an alternative decision assignment at the current decision level that results in the same conflict. The main motivation for identifying UIPs is to reduce the size of learnt clauses.

In the implication graph, there is a UIP at decision level  $d$  when the number of literals in  $\mathcal{C}_L$  assigned at decision level  $d$  is 1 [11].

**Definition 17** Let  $\phi(\mathcal{C}, d)$  be the number of literals in  $\mathcal{C}$  assigned at decision level  $d$ :

$$\phi(\mathcal{C}, d) = |\{l \in \mathcal{C} \mid \delta(l) = d\}| \quad (4.9)$$

As a result, the clause learning procedure with UIPs is given by:

$$\mathcal{C}^{d,i} = \begin{cases} \alpha(\varepsilon) & \text{if } i = 0 \\ \mathcal{C}^{d,i-1} \odot \alpha(l) & \text{if } i \neq 0 \wedge \xi(\mathcal{C}^{d,i-1}, l, d) = 1 \\ \mathcal{C}^{d,i-1} & \text{if } i \neq 0 \wedge \phi(\mathcal{C}^{d,i-1}, d) = 1 \end{cases} \quad (4.10)$$

Equation 4.10 allows creating a clause containing literals from the learnt clause until

the first UIP is identified. It is simple to develop equations for learning clauses for each additional UIP. However, this is unnecessary in practice, the most effective CDCL SAT solvers stop clause learning when the first one is reached. Moreover, clause learning could potentially stop at any UIP. But, considering the largest decision level of the literals of the clause learnt at each UIP, the clause learnt at the first UIP is guaranteed to contain the smallest one. What follows from this is that choosing the clause learnt at the first UIP implies the highest backtrack jump in the search tree [11].

**Example 12.** Consider again Example 10. The default clause learning procedure would learn the clause  $(p \vee t \vee y)$  (see Example 11). However, by taking into consideration that  $s = \text{true}@5$  is a UIP, applying the clause learning of Equation 4.10 yields the resulting clause  $(\neg s \vee y)$ . One advantage of this new clause is that it has one less literal than the learnt clause from Example 10.

Clause learning finds other applications besides the key efficiency improvements to CDCL SAT solvers. One example is *clause reuse*. In a large number of applications, clauses learnt from a given CNF formula can often be reused for related CNF formulae. The basic concept is to reuse constraints on the search space which are deduced while checking a previous instance, for speeding up the SAT checking of the current one [52].

Moreover, for unsatisfiable subformulae, the clauses learnt by a CDCL SAT solver, as formalised in Definition 16, encode a resolution refutation of the original formula. Given the way clauses are learnt in this solvers, each learnt clause can be explained by a number of resolution steps, each of which is a trivial resolution step. As a result, the resolution refutation can be obtained from the learnt clauses in linear time and space on the number of learnt clauses.

For unsatisfiable formulae, the resolution refutations obtained from the clauses learnt by a SAT solver serve as certificate for validating the correctness of the SAT solver [11]. Besides, resolution refutations based on clause learning find practical applications, including hardware model checking [41].

## 4.3 Modern SAT Solvers

Annual competitions have led to the development of dozens of clever implementations of SAT solvers, allowing many techniques to be explored and creating an extensive suite of real-world instances as well as challenging hand-crafted benchmarks problems [29]. Apart from conflict analysis, modern solvers include techniques like lazy data structures, search restarts, conflict-driven branching heuristics and clause deletion strategies [11].

In 2001, researches at Princeton University designed a complete solver, which they named Chaff [42], that, as most solvers, is an instance of the DPLL search procedure with

a number of enhancements aiming in efficient applications. Their algorithm was later used as base for numerous well-succeed implementations (as [16] and [55], for instance). Chaff achieved significant performance gains through careful engineering of all aspects of the search — especially a particularly efficient implementation of unit propagation and a novel low overhead decision strategy. It was able to obtain, at the time, one to two orders of magnitude performance improvement on difficult SAT benchmarks [42].

Alongside the optimized unit propagation, Chaff also designed a decision heuristic, which they called *Variable State Independent Decaying Sum (VSIDS)*. Decision assignment consists of the determination of which new variable should be assigned a value, in each decision level. There are several strategies in the literature to try and solve this problem, but by that far, there was a lack of clear statistical evidence supporting one strategy over others, making difficult to determine what differs a good decision from a bad one [42]. With that in mind, and also after some testing with a few available strategies, Chaff’s designers thought they could come up with a considerably better heuristic for the range of problems on which Chaff was being tested. The VSIDS strategy is described as follows:

1. Each literal has a counter, initialized to 0.
2. When a clause is added to the clause database, the counter associated with each literal in the clause is incremented.
3. The unassigned literal with the highest counter is chosen at each decision.
4. Ties are broken randomly by default.
5. Periodically, all the counters are divided by a constant.

Overall, this strategy can be viewed as attempting to satisfy the conflict clauses but, particularly, attempting to satisfy *recent* conflict clauses, due to the fifth item. Since difficult problems generate many conflicts, the conflict clauses dominate the problem in terms of literal count, so this approach distinguishes itself in how it favors the information generated by recent conflict clauses [42]. To this day, CDCL SAT solvers crucially depend on the VSIDS decision heuristic for their performance [40].

A few years later, Sörensson and Een developed a SAT solver with conflict clause minimization, named *MiniSat* [55], that stayed for a while as the state-of-the-art solver. MiniSat is a popular high-performance satisfiability solver that implements many well-known performance heuristics in a concise manner. It has won several prizes in the SAT 2005 competition, and has the advantage of being open-source.

MiniSat is the implementation of the solver described in [22]. It corresponds to a minimalist Chaff-like SAT solver based on clause learning by conflict analysis. A number

of small improvements has been made with respect to the original Chaff. Two important features are the incremental SAT interface, and the support for user defined boolean constraints. Although none of these improvements are really relevant for the SAT competition, they are important when using MiniSat as an integrated part of a bigger system [55]. In this sense, a user application can specify and solve SAT-problems, through MiniSat’s external interface, sending its own previously known boolean constraints.

MiniSat’s version of VSIDS makes some simple changes to the original one, as follows:

1. Each *variable* has a counter.
2. Instead of a decay factor, variable counters are “bumped” with larger and larger values in a floating point representation. When very large values are encountered, all counters are scaled down.
3. At every certain rate, a random decision is made instead. This factor is set at run-time.

In addition, MiniSat’s implementation of VSIDS always keeps the variables in order by placing them in an array-based priority queue.

In 2009, a MiniSat based solver appeared claiming to predict the quality of learnt clauses. *Glucose* [4] is based on a scoring scheme introduced earlier on the same year by Audemard and Simon in [5]. The name of the solver is a contraction of the concept of “glue clauses”, a particular kind of clauses that Glucose detects and preserves during the search.

Detecting what is a good learnt clause in advance is a challenge, and of first importance: deleting useful clauses can increase time dramatically, in practice [4]. To prevent this, solvers have to let the maximum number of clauses grow exponentially. On very hard benchmarks, CDCL solvers face memory problems and, even if they do not, their greedy learning scheme deteriorates the performance. In [5], Audemard and Simon showed that a very simple static measure on clauses can dramatically improves the performance of the publicly available version of MiniSat of that time.

In their studies, Audemard and Simon observed a strong relationship between the overall decreasing of decision levels, presented by most solvers running on a industrial set of benchmarks, and the performance of them [5]. In this sense, they thought that finding the part of the learning schema that enforces this decreasing rate, could lead to identifying good learnt clauses in advance.

During the search, each decision is often followed by a large number of unit propagations. All literals from the same level are called “blocks” of literals in the later. Intuitively, at the semantic level, there is a chance that they are linked with each other by direct dependencies. The idea is that a good learning schema should add explicit links between

independent blocks of decision literals. If the solver stays in the same search space, such a clause will probably help reducing the number of next decision levels in the remaining computation [5].

In Glucose, literals in a clause are partitioned with respect to their decision level. The *Literals Blocks Distance (LBD)* of a clause is exactly the number of subsets of its literals, divided accordingly to the current assignment. This measure is static, even if updated during the search (the LBD score of a clause can be re-computed when the clause is used in unit-propagation). For instance, it is easy to understand the importance of learnt clauses of LBD 2: they only contain one variable of a previous decision level, and, later, this variable will be “glued” with the block of literals propagated above, no matter the size of the clause. These clauses are very important during the search, and they receive a special name: “glue clauses”.

Experiment results lead Audemard and Simon to conclude that this strategy works in practice. In most of the cases, the decreasing rate of decision levels was indeed accelerated.

One can notice that these last decades showed an enormous progress in the performance of SAT solvers. We have seen these modern solvers increasingly leaving their mark as a general-purpose tool, which provides a “black-box” procedure that can often solve hard structured problems with over a million variables and several million constraints.

We believe that we can take advantage of the theoretical and practical efforts that have been directed in improving the efficiency of such solvers. As mentioned in Chapter 3, the KSP prover loses in performance when there is a high number of propositional symbols in just one particular level. We already know that these sets are satisfiable, as the specific normal form used always generates satisfiable sets of propositional clauses. If we feed a SAT solver, like MiniSat or Glucose, with these satisfiable sets, each time a conflict is identified, we think that the learnt clauses may help KSP to reduce the time spend during saturation.

# Chapter 5

## Discussion and Future Work

The first chapters of this work set the ground theory needed to understand the scenario in which our work in progress fits. Chapter 2 introduced the propositional modal language which is the main focus of this work:  $K_n$ . We have seen that modal logics extend classical logic by adding operators to express one or more of different modes of truth. The key goal behind these operators is to allow the reasoning over relations over the abstractions we call possible worlds. Thus, the information holding at worlds accessible from the current one — via an accessibility relation — is available to examination.

$K_n$  is the extension of the classical propositional logic plus the unary operators  $\Box_a$  and  $\Diamond_a$ , whose reading are “is necessary from the point of view of an agent  $a$ ” and “is possible from the point of view of an agent  $a$ ”, respectively.  $K_n$ ’ syntax follow directly from the syntax of classical propositional language, also considering constructions with the modal operators as well-formed formulae.

On the other hand, the semantics of  $K_n$  is presented in terms of Kripke models. A set of worlds, their binary accessibility relations, labelled by an agent, and a valuation function define a structure known as a Kripke model. The satisfiability and validity of a formula depend on this structure.

Finally, Chapter 2 also presented what proof systems and normal forms are. Recall that we are interested in sound and complete calculus for  $K_n$ , as well as normal form translations that preserve satisfiability of formulae.

In Chapter 3, we mentioned  $KSP$ , the theorem prover presented in [46]. Earlier in the same chapter, we briefly introduced clausal resolution, the base of the modal-layered calculus behind  $KSP$ . As we have seen, resolution is a simple and adaptable proof system for propositional classical logic, as it has only one inference rule that is thoroughly applied. This rule entails the well known resolution principle.

The calculus presented for  $K_n$  adds a few more rules, as it also has to handle with modal reasoning. This calculus makes use of labelled resolution in order to avoid unnecessary

application of such rules. Thus, it requires a translation of formulae into a more expressive language, where labels are used to express semantic properties. Formulae in  $K_n$  is, then, translated into a layered normal form called  $SNF_{ml}$ . We showed that a formula in  $SNF_{ml}$  is a conjunction of clauses where the modal level in which they occur is made explicit in the syntax. We referred the reader to where one can find the proofs of correctness of such calculus and translation.

KSP implements this modal labelled resolution calculus. It was designed to support experimentation with different combinations of refinements. KSP performs well if the set of propositional symbols are uniformly distributed over the modal levels. However, when there is a high number of propositional symbols in just one particular level, the performance deteriorates. One reason is that the specific normal form used always generates satisfiable sets of propositional clauses (clauses without modal operators). As resolution relies on saturation, this can be very time consuming.

We saw in Chapter 4 that SAT solvers can often solve hard structured problems with over a million variables and several million constraints [29]. We believe that we can take advantage of the theoretical and practical efforts that have been directed in improving the efficiency of such solvers.

Also in Chapter 4, we discussed the role of clause learning in the successful widespread use of SAT. We saw that the main idea behind Conflict-Driven Clause Learning solvers is to cache “clauses of conflict” as learned clauses, and to use this information to prune the search in a different part of the search space. The conflict analysis procedure consists of analysing the most recent conflict and learning a new clause from it.

CDCL solvers have been successfully used, for instance, as a tool for managing learnt clauses among a parallel, memory shared, solver [7], as implementation basis for hybrid logics solvers [51], and as plugins for integrated development environment [39]. Furthermore, they keep showing outstanding results in SAT competitions [6, 10].

In [28], Giunchiglia et. al. present a set of SAT-based decision procedures for various classical modal logics. These procedures are built on top of a SAT solver. This differ from our work in the sense that we are not developing a system from an existing SAT solver. We are trying to improve the efficiency of a clausal resolution based prover for the basic multimodal logic, using a CDCL SAT solver.

Our implementation, which is work in progress, feeds a CDCL SAT solver with the satisfiable sets of clauses generated by the translation procedure. Each time a conflict is identified in these sets, due to unit propagation from some variable assignment, one or more new clauses are learnt from the conflict analysis procedure. This procedure analyses the structure of unit propagation and decides which literals to include in the new clauses [11]. As we already know that these sets are satisfiable, we are not particularly

interested in the satisfying assignment generated by the SAT solver, but we believe that by carefully choosing the set of clauses and making use of the learnt clauses generated by the solver, we may be able to reduce the time KSP spends during saturation.

## 5.1 MiniSat vs Glucose

In the Section 4.3, we gave an overview of two of the most efficient SAT solvers known to this date: MiniSat and Glucose. Both solvers are great candidates to be combined with KSP. This section discuss these two implementations.

As we have seen, MiniSat is a minimalistic solver, that implements a variation of Chaff’s Variable State Independent Decaying Sum. MiniSat stayed for a long as the state-of-the-art solver. To these days, this solver keeps its importance as a tool used as an integrated part of a different system. In this sense, MiniSat’s public interface and support for user defined constrains are key features.

It is through MiniSat’s interface, taken from [22] and illustrated below, that a user application can specify and solve SAT problems [22].

```
class Solver _ Public interface
  var newVar()
  bool addClause(Vec<lit> literals)
  bool add...(...)
  bool solve(Vec<lit> assumptions)

  Vec<bool> model //If found, this vector has the model
```

The “*add...*” method should be understood as a place-holder for additional constraints implemented in an extension of MiniSat. For a standard SAT problem, the interface is used in the following way: Variables are introduced by calling “*newVar*”. From these variables, clauses are built and added by “*addClause*”. Trivial conflicts, such as two unit clauses  $\{p\}$  and  $\{\neg p\}$  being added, can be detected by this method, in which case it returns **false**. If no such trivial conflict is detected during the clause insertion phase, “*solve*” is called with an empty list of assumptions. It returns **false** if the set of clauses added is unsatisfiable, and **true** if it is satisfiable, in which case the model can be read from the public vector “*model*”. If the solver returns satisfiable, new constrains can be added repeatedly to the existing database and “*solve*” may execute again.

The search procedure of a modern solver is usually the most complex part to implement [22]. Heuristically, variables are picked and assigned values until the propagation detects a conflict. At this point, a conflict clause is construct and added to the clauses

database. Variables are then unassigned by backtracking until the conflict clause becomes unit, from which point this unit clause is propagated and the search process continues.

The learning procedure of MiniSat starts when a constraint becomes impossible to satisfy under the current assignment. The conflicting constraint is then asked for a set of variable assignments that make it contradictory. For a clause, this would be all the literals of the conflict clause. Each of the variable assignments returned must be either a decision or a implied variable. The propagation constraints are in turn asked for the set of variable assignments that forced the propagation to occur, continuing the analysis backwards. The procedure is repeated until some termination condition is fulfilled, resulting in a set of variable assignments that implies the conflict. A clause prohibiting that particular assignment is added to the clause database. This learnt clause must always, by construction, be implied by the original problem constraints.

Learnt clauses serve two purposes: they drive the backtracking (as showed in Section 4.2) and they speed up future conflicts by caching the reason for the conflict.

The main mechanism in which MiniSat runs, taken from [22], is illustrated bellow.

```

loop
  propagate() /*propagate unit clauses*/
  if not conflict then
    if all variables assigned then
      return satisfiable
    else
      decide() /*pick a new variable to assign a value*/
  else
    analyze() /*analyze conflict and add a conflict clause*/
    if top-level conflict found then
      return unsatisfiable
    else
      backtrack() /*undo assignments*/

```

To use this prover in our work, we would have to interact with the public interface of an instance of MiniSat, feed it with the clauses at a specific modal level, and capture the learnt clause (or clauses) returned by the procedure *analyse()*, when a conflict is identified. Finally, we would add this clause to the set of propositional clauses of KSP, at the corresponding modal level, hoping this new clause reduces the time KSP spends dealing with propositional logic. We believe that only a few changes in the source code of MiniSat would be necessary.

On the other hand, we have Glucose, which dramatically improved the performance of the solver that it was based on: MiniSat [4], claiming to predict the quality of learn

clauses. As we are interested in the clauses a solver will learn from the set we feed it, this may highlight Glucose from other SAT solvers. However, we still have to investigate if the metrics they use to judge this so called quality, really apply to our problem.

Most CDCL solvers present a decreasing of decision level on most industrial benchmarks [5]. In their studies, Audemard and Simon observed a strong relationship between this overall decreasing and the performance of the solver [5]. They refer as *look-back justification* the estimated number of conflicts before reaching the first decision level, which concludes the search. One curious thing they noticed was that the look-back justification is also strong when the solver finds a solution, i.e., a satisfying assignment. This suggested that, on satisfiable instances of problems, the solver does not correctly guess a value for a literal, but learns that the opposite value directly leads to a contradiction. In this sense, they thought that finding the part of the learning schema that enforces the decreasing rate of decision levels, would lead to identifying good learnt clauses in advance.

As we saw in Section 4.3, during the search, each decision is often followed by a large number of unit propagations. All literals from the same level are called “blocks” of literals in the later, meaning that there is a chance that they are linked with each other by direct dependencies. The idea is that a good learning schema should add explicit links between independent blocks of decision literals. If the solver stays in the same search space, such a clause will probably help reducing the decision levels in the remaining computation.

We also saw that Glucose partitions the literals in a clause with respect to their decision level. The LBD of a clause is exactly the number of subsets of its literals, divided accordingly to the current assignment. The LBD score of each learnt clause is computed and stored when it is produced. This measure is static, even if updated during the search (LBD score of a clause can be re-computed when the clause is used in unit-propagation).

For instance, it is easy to understand the importance of learnt clauses of LBD 2: they only contain one variable of a previous decision level, and, later, this variable will be “glued” with the block of literals propagated above, no matter the size of the clause. These clauses are very important during the search, and they receive the special name “glue clauses”.

Experiment results lead Audemard and Simon to conclude that this strategy works in practice. In most of the cases, the decreasing rate of decision levels was indeed accelerated.

The question we face is to either go with the minimalism of MiniSat, or to bet on Glucose’s robust search for a good learnt clause.

We believe that the amount of work to combine KsP with either provers would be quite close. Since Glucose is based on MiniSat, they share a similar user interface. Other than that, both provers are written in C++, with a comparable amount of documentation. MiniSat has an experimental version in C, a language we are more familiar with, although,

it is a distant version from the last public release of MiniSat, in 2010. Glucose’s last release, on the other hand, is from 2016.

## 5.2 Future Work

We are inclined to go with Glucose as the chosen solver, because it has a newer release, and because of all the effort to produce the so called good clauses seems to be worth it. Although, we are remaining flexible. Our studies, the overview of the solvers’ code and modest testing lead us to it, so we are confident. However, if in practice we suspect that MiniSat (or any other solver), would actually work better for our purpose, we intend to revisit this decision. In the meantime, we will be moderately changing Glucose to best fit our necessities.

Then, we will focus on integrating the chosen solver with KSP. During the main loop of KSP, numerous system calls may be made to execute an instance of our own slightly different version of the solver, passing as parameters, propositional clauses at the specific modal level. This integration will be implemented as a choice to the user, as most strategies of KSP, to maintain the experimentation support.

When the implementation is working well, is time to define our hypothesis, the metrics for testing, and choose the benchmarks.

Finally, we will put KSP through a large amount of test. Then all the results will be collected and critically analysed, aiming to evaluate the impact of combining the SAT solver with KSP.
